"*To the solid ground*
Of Nature trusts the mind which builds for aye."—WORDSWORTH

London
MACMILLAN AND CO., LIMITED
NEW YORK: THE MACMILLAN COMPANY

RICHARD CLAY AND SONS, LIMITED,
LONDON AND BUNGAY.

INDEX

A-Birding on a Bronco, Florence A. Merriam, 387
Abbadie (A. T. d'), Death of, 494; Obituary Notice of, 510
Abbe (Prof. Cleveland), St. Medard's Day and Rain, 258
Abbott (Charles C.), Notes of the Night, and other Outdoor Sketches, 77
Abbott (W. J. L.), the Cromer Forest Bed worked Flints, 300
Abegg (R.), Dielectric Constants at Low Temperatures, 309
Abney (Capt. W. de W., F.R.S.), Apparatus for giving Diagrams of Efficiency of Photographic Shutter, 119; Photography in Colours, 318
Absorption of Light, the Atmospheric, W. E. Plummer, 235
Acceleration, Rev. Edward Geoghegan, O.J.L., 271
Acetylene, the Explosive Properties of, Prof. A. Smithells, 42; Laboratory use of, A. E. Munby, 486; Thos. Fletcher, 535
Achrometer, the, A. M. Bloch, 96
Acoustics: Musical Tubes, R. T. Rudd, 165; Kinematic Model of Hertz-wave Transmission, Dr. S. P. Thompson, 525; Perception of Sound Direction and Distance, Dr. A. A. Gray, 599
Acquired Characters, Prichard and, Wilfred Mark Webb, 342; Prof. R. Meldola, F.R.S., 342
Actinometric Observations on Mount Blanc, MM. Crova and Houdaille, 143
Aerodrome, Prof. Langley's, 401
Aerodynamics: Sailing Flight, S. E. Peal, 271
Aeronautics: Ascent by Kites, Lieut. H. D. Wise, 327; the International Aerostatic Ascents, 398; Prof. Langley's Aerodrome, 401
Affinities of *Hesperornis*, the, Prof. O. C. Marsh, 534
Africa: the Tsetse Fly, Surgeon-Major Bruce, 47; African Rinderpest, Sir John Kirk, K.C.B., F.R.S., 53; Dr. Koch's Reports on Rinderpest, 450; Return of Lieut. Hourst's Niger Expedition, 133; Big Game Preserve established in British Central Africa, 182; the Geodetic Survey of South Africa, Sir C. W. Wilson, F.R.S., 226; the Fish of Lake Tanganyika, J. E. S. Moore, 258; Geography of Africa, Edward Heawood, 364; Natural History of North Nyasa, Alexander Whyte, 398; Travels in West Africa, Mary H. Kingsley, 416; Manikaland, J. E Farnum, 515; Deposits of Nile Basin, Prof. J. W. Judd, F.R.S., 548; *Sigillaria* and *Glossopteris* in South Africa, A. C. Seward, 550; David Draper, 550
Agafonoff (S.), Absorption of Ultra-violet Light by Crystals, 350; Comparison between absorption by Crystalline Media of Luminous Rays and Röntgen Rays, 623
Agamennone (Dr. G.), Earthquake of April 16 in N.W. Asia Minor, 182
Agriculture: Note on *Plasmodiophora brassicæ*, Prof. M. C Potter, 33; Sparrows and Wheat, F. G. Brook-Fox, 33; Sugar-Cane Growth in Queensland, 60; the Book of the Dairy, W. Fleischmann, 122; Death and Obituary Notice of Prof. Emil von Wolff, 134; the Parasitic Diseases of Poultry, Fred. V. Theobald, 196; Reduction of Nitrates in Arable Earth, 383; Papilionaceous Plants and Nitragen, Prof. W. Somerville, 399; the Value of Irrigation Canals in India, 404; Algæ, Bacteria and Free Nitrogen, P. S. Kossovich, 428; Agricultural Teaching at Oxford, Robert Warington, F.R.S., 449; Prof. W. Somerville's Manurial Trials, 471; the Cultivation of Oats, 496; Effect of Electricity on Plants, A. S. Kinney, 514; Use of Fungus for destroying Locusts, Dr. W. A. Soga and H. P. Browne, 514; Report of Observations of Injurious Insects and Common Farm Pests during the Year 1896, with Methods of Prevention and Remedy, Eleanor A. Ormerod, 557; Agricultural Experiments in Plots and Pots, 596; Farm and Garden Insects, Prof. Wm. Somerville, 605
Aguiar (A. d'), Examination of White Wines for Coal-tar Dyes, 431
Ainsworth (W. F.), Death of, 108
Air: Electrification of, by Röntgen Rays, Lord Kelvin, F.R.S., Dr. J. C. Beattie, Dr. Smoluchowski de Smolan, 199; On the Conductive Effect produced in Air by Röntgen Rays and by Ultra-violet Light, Lord Kelvin, F.R.S., Dr. J. C. Beattie, Dr. Smoluchowski de Smolan, 343; Compressed Air Illness or so-called Caisson Disease, E. Hugh Snell, 411; Frictional Effect of Trains on Air, Prof. F. E. Nipher, 454; Liquefaction of, by Self-intensive Refrigeration, Dr. W. Hampson, 485
Airy (Sir George Biddell, Astronomer Royal), Autobiography of, 145
Aitken (R. G.), Double Star Measures, 280
Alaska, Reindeer in, Sheldon Jackson, 39; Severe Winter Weather in, Sheldon Jackson, 39; Gold in, Prof. C. D. Walcott, 298
Alcohol as Disinfectant for Surgical Instruments, Dr. Robert Randolph, 60; the Extraction of Alcohol-producing Ferment from Yeast, Dr. E. Buchner, 442; Toxicity of Alcohol, M. Picaud, 600
Alden (Dr. C. H.), the United States Army Identification Method, 59
Alexander (Thos.), Equilibrium of a Cylindrical Shell, 366
Algæ, Histology of the Blue-green, Prof. Zacharias, 21
Algæ, Polymorphism of the Green, and the Principles of their Evolution, Prof. Chodat, 20
Algebra: Lehrbuch der Algebra, Heinrich Weber, 25, 481; the Symbols of applied Algebra, Prof. Oliver J. Lodge, F.R.S., 246, 293, 317; C. S. Jackson, 293, 366
Algol Variable + 17° 4367 W Delphini, the, Prof. E. C. Pickering, 260
Allen (John A.), Tables for Iron Analysis, 77
Alloys of Copper and Zinc, G. Charpy, Dr. T. K. Rose, 130
Alloys: Fourth Report to Research Committee, Prof. Roberts-Austen, 377
Alps: Sport in the Alps in the Past and Present, W. A. Baillie-Grohman, Prof. T. G. Bonney, F.R.S; Aus den Alpen, R. von Lendenfeld, Prof. T. G. Bonney, F.R.S.; Chamounix and the Range of Mont Blanc, Edward Whymper, Prof. T. G. Bonney, F.R.S., 102
Alps: The Japanese, Mountaineering and Exploration in the, Rev. Walter Weston, Prof. T. G. Bonney, F.R.S., 102
Alps: The New Zealand, Climbs in the, E. A. Fitzgerald, Prof. T. G. Bonney, F.R.S., 422
Alterations of Personality, Alfred Binet, 389
Alternations of Generations in Plant Life, on the, Right Hon. Sir Edw. Fry, F.R.S., 422
America: The Princeton Sesquicentennial, Dr. Wm. H. Hale, 43; Bulletin of American Mathematical Society, 46, 188, 309, 380, 524, 574; American Journal of Science, 91, 188, 308, 406, 476; Leonid Meteors in America, 137; Artesian Basins in North, Gibb Maitland, 182; American Journal of Mathematics, 308; Researches on the Antiquity of Man in the Delaware Valley and the Eastern United States, Henry C. Mercer, 459; the Dinosaurs of North America, Othniel Charles Marsh, 463; Glaciers of North America, Israel C. Russell, Prof. T. G. Bonney, F.R.S., 556; Grasses of North America, W. J. Beal, 557; Survey of the Tides and Currents in the Gulf of St. Lawrence, 595
Amherst (Hon. Alicia), a History of Gardening in England, 75

Amsterdam Academy of Sciences, 192, 431, 455, 527, 551
Anatomy: Text-Book of Comparative Anatomy, Dr. Arnold Lang, 4; Use of X-Rays in Research, Ch. Remy and G. Contremoulins, 48; Death of Dr. L. J. Sanford, 205; Death of Dr. Luigi Calori, 231; Death of Dr. Josef von Gerlach, 277; Death of Dr. Salvatore Trinchese, 348; Experiments on Distribution of Posterior Root-Fibres of Spinal Nerves, Prof. C. S. Sherrington, F.R.S., 356; Cataleptoid Reflexes in Monkey, Prof. C. S. Sherrington, F.R.S., 357; New Method of Preparing Specimens, N. Melnikoff-Rasvédenkoff, 359; Results of Staining Brain by Chrome-Silver Method, 359; Reciprocal Innervation of Antagonistic Muscles, Prof. C. S. Sherrington, F.R.S., 381
Anderson (Henry J. C.), Whirlwind on "Rydal Water," 5
André (G.), Arabinose, 24; Estimation and Transformation of Pyrophosphoric Acid, 95; Estimation of Pyrophosphoric Acid, 383
Andrews (G. F.), the "Spinning" Activities of Protoplasm in Echinoderm Eggs, 615
Andrews (Thomas, F.R.S.), the Loss of Strength in Iron and Steel by Use, 418
Anemometers, Robinson and Pressure-Tube, compared, C. E. Peek, 372
Aneroids, Temperature-Coefficent of, L. H. Siertsema, 431
Angot (Alfred), the Aurora Borealis, 173
Animal Life possible in the Absence of Bacteria, Is, G. Nuttall and H. Thierfelder, 238
Animals at Work and Play; their Activities and Emotions, C. J. Cornish, 52
Annable (H.), Formation of Substituted Oxytriazoles from Phenylsemicarbazide, 310
Annales of St. Petersburg Central Physical Observatory, 591
Anniversary of the Foundation of the Naples Zoological Station, the Twenty-fifth, H. M. Vernon, 586
Anniversary Meeting of the Royal Society, the, 111
Anode and Kathode, Röntgen Rays and Phenomena of the, Edward P. Thompson, 386
Anodes, Heating of, in X-Ray Tubes, Walter Chamberlain, 198; A. A. C. Swinton, 225
Anthropology: Die Formen der Familie und die Formen der Wirthschaft, Prof. Grosse, Edward B. Tylor, F.R.S., 51; the Mouthe Cave, M. Rivière, 55; Drawings on Rocks of La Mouthe Cave, M. Rivière, 575; the United States Army Identification Method, Dr. C. H. Alden, 59; Ancient Assyrian Bow found in Egypt, Henry Balfour, 71: Tailed Men in Indo-China, Paul d'Enjoy, 82; Ethnography of New Georgia, Lieut. B. T. Somerville, 143; Anthropological Institute, 143, 189; the Anthropological History of Southern Russia, M. Zaborowski, 184; the Symbolic Use of Wampum, Horatio Hale, 189; the Reading, Writing, and Arithmetic of the Neolithic Troglodytes, M. Ed. Piette, 229; on Certain Vestigial Characters in Man, Dr. Walter Kidd, 236; the Svasiika, S. E. Peal, 248; Death of Horatio Hale, 257; Selection in Man, Dr. John Beddoe, 260; Intermediate Links between Man and Lower Animals, Dr. Munro, 263; Marriage Observances of American Aborigines, W. J. McGee, 302; the Successive Adoption of the Mechanical Powers, Dr. O. T. Mason, 469; Kyz-Kiyik, the Wild Men of Tibet, P. K. Kozloff, 541
Anti-Toxin, a New Diphtheria, Dr. Smirnow, 597
Antiquity of certain Curved Knives, the, Dr. Otis T. Mason, 534
Appleyard (Mr.), Electrical Trevelyan Rockers, 23
Appleyard (Rollo), Liquid Coherers and Mobile Conductors, 525
Applied Bacteriology, T. H. Permain, C. G. Moore, Dr. A. A. Kanthack, 413
Archæology: Remarkable Find of Chud Implements near Perm, M. Sergueeff, 82
Archibald (Douglas), the Long Period Weather Forecasts of India, 85
Architecture, Naval: Institution of Naval Architects, 571; Water-Tube Boilers in *Powerful* and *Terrible*, A. J. Durston, 571; Application of Compound Steam Turbine to Marine Propulsion, Hon. Charles Parsons, 571
Artesian "Basins" in North America, Gibb Maitland, 182
Arctic: Dr. Nansen's Narrative, 11; the Early Life of Nansen, W. C. Brögger, Nordahl Rohlfsen, Dr. Hugh Robert Mill, 201; Nansen's Arctic Expedition, 352; Fridtjof Nansen's "Farthest North," Dr. Hugh Robert Mill, 393; the North Polar Problem, Dr. Nansen, 495; the Geology of Greenland, Prof. R. S. Tarr, 13; the Austro-Hungarian Map of Franz Josef Land, Prof. Ralph Copeland, 29; Arthur Montefiore-Brice, 52; Reindeer and Severe Winter Weather in Alaska, Sheldon Jackson, 39; the Polar Limit of True Forest Land, K. Roder, 349; Lieut. Peary's projected New Polar Expedition, 371; Lieut. Peary's Plan to reach the North Pole, 564; Arctic Sea Ice as a Geological Instrument, R. S. Tarr, 476; Scientific Kite-work in Arctic Regions, Dr. Harvey, 598
Arendsee, Depth of the, Dr. W. Halbfass, 234
Argon: Uniform Distribution in Atmosphere of, Th. Schlœsing, 48; the Spectra of, J. Trowbridge and J. W. Richards, 308; Argon and Nitrogen in Blood, P. Regnard and Th. Schlœsing, 383; Argon in Plants, Dr. G. Tolomei, 399
Armstrong (Dr. Henry E., F.R.S.), Osmotic Pressure and Ionic Dissociation, 78; the Direct Synthesis of Optically Active Proteid-like Substances, 341; the Need of Organising Scientific Opinion, 409, 433; 3′-Bromo-β-Naphthol, 165
Aryan Medical Science, a Short History of, H.H. Sir Bhagvat Sinh Jee, 221
Ashworth (J. R.), Discharge of Electricity by Phosphorus, 225
Asia, Sven Hedin's Explorations in Central, 58, 589; Mongolia and the Mongols, A. Pozdnéeff, 603
Asphalt, Origin of, Stanislas Meunier, 239
Asphalt Springs of El Menito, the, Baron H. Eggers, 470
Assyrian Bow found in Egypt, Ancient, Henry Balfour, 71
Aston (E.), Oxidation Products of αγ-Dimethyl-α′-Chloropyridine, 623
Astronomy: Our Astronomical Column, 14, 41, 61, 84, 110, 137, 163, 183, 208, 235, 260, 279, 303, 329, 352, 373, 401, 421, 447, 472, 498, 516, 544, 566, 592, 616; Strassburg Observatory, 14; Himmel und Erde, 15, 208; Elements of Astronomy, Sir Robert Ball, F.R.S., 28; Mars, 41; Prof. Schiaparelli, 516; Mars in August last, Prof. V. Cerruli, 14; Mists on Mars, M. Flammarion, 235; the Canals of Mars, Herr M. Teoperberg, 280; Origin of Mars' Canals, Dr. J. Joly, F.R.S., 335; the Polar Cap of Mars, 303; Observations of Mars at Meudon, M. Perrotin, 401; the Ellipticity of the Disc of Mars, Prof. W. Schur, 421; Comet Perrine, 1896, December 8, 208, 279; Ephemeris for Comet Perrine, Prof. H. Kreutz, 41; Prof. Holden, 42; Otto Knopf, 110; Sunspots, Comets, and Climate Variations, Herr Johannes Unterweger, 42; the Leonids, 42, 84; the Leonid Meteor Shower, W. F. Denning, 54, 153; Dr. W. J. S. Lockyer, 54; C. T. Whitmell, 54; Leonids of November 15 (a.m.), 1896, Prof. A. S. Herschel, F.R.S., 173; Leonid Meteors in America, 137; Hypothesis of Successive Transmission of Gravity, Prof. J. McMahon, 46; Celestial Mechanics, Prof. W. E. Brown, 46; Disaggregation of Comets, O. Callandreau, 47; Partial Impact of Celestial Bodies, Prof. A. W. Bickerton, 61; the Companions of Procyon and Sirius, 62; the Satellite of Procyon, Isaac W. Ward, 153; the Companion to Procyon, Prof. Schaerberle, 498; the Period of Sirius' Companion, 329; Brisbane Astronomical Society, 62; Bulletin de la Société Astronomique de France, 62, 592; a New Speculation on the Past and Future Temperature of the Sun and Earth, 77; Stars with Peculiar Spectra, Mrs. Fleming, 84; Death of Dr. Benjamin Gould, 108; Obituary Notice of, 132; the Astrophysical Journal, 110; Planetary Notes, 111; a Companion to θ Scorpii, Dr. T. J. J. See, 111; a New Spectroscopic Binary in Puppis, 137; the Spectrum of ζ Puppis, 352; Relative Motion of Stars in the Line of Sight, Prof. E. C. Pickering, 137; Formulæ for Computing Wave-Lengths, 137; Autobiography of Sir George Biddell Airy, Astronomer Royal, 145; Diagrams of Terrestrial and Astronomical Objects and Phenomena, R. A. Gregory, 149; Death and Obituary Notice of Johan August Hugo Gyldén, 158; Bureau des Longitudes, 163; the System of the World, 163; Companion to the Observatory, 163; Death and Obituary Notice of Sidney Waters, 181; Mountain Observatories, 183; Observations of Saturn, Herr A. Anton Wonaszek, Herr L. Brunner, 183; Karlsruhe Meridian Observations, 183; the Western Australia Government Observatory, 183; Solar Motion as Gauge of Stellar Distances, Prof. Simon Newcomb, 191; Hindu Astronomy, W. Brennand, W. T. Lynn, 193; Astronomical Society of France, 208; Shooting Stars of January 2, Dr. H. C. Sorby, F.R.S., 225; W. F. Denning, 247; the Total Solar Eclipse of August 9, 1896, M. Deslandres, 235; the Total Solar Eclipse of August 8, 1896, 447; Results with Prismatic Camera during 1896 Eclipse, J. Norman Lockyer, F.R.S., 263; Russian Observations of the Corona of August 9, 1896, Baron Nicolas Kaulbars, 298; the Melbourne Ob-

servatory, 235; the Wonderful Universe, Agnes Giberne, 246; Celestial Eddies, J. Norman Lockyer, F.R.S., 249; Arthur Mee's Amateur's Almanac, 260; the Algol Variable + 17° 4367 W Delphini, Prof. S. C. Pickering, 260; Comet Notes, 261; the Universal Meridian, 261; an Introductory Treatise on the Lunar Theory, Prof. E. W. Brown, 266; Double-Star Measures, R. G. Aitken, 280; Oxygen in the Sun, Herren Runge and Paschen, 303; Lewis Jewell, 447; the Question of Carbon in Bright Line Stars, J. Norman Lockyer, F.R.S., 304, 341; Dr. William Huggins, F.R.S., 316; Tables for Finding Latitude Variations, Prof. S. C. Chandler, 329; the Trifid Nebula, Prof. Pickering, 329; Heat Rays of Great Wave-Length, H. Rubens, E. F. Nichols, 329; Cours d'Astronomie, M. B. Baillaud, 339; the Period of Rotation of Jupiter's Spots, A. A. Nyland, 352; the Orbit of Jupiter's Fifth Satellite, Dr. Fritz Cohn, 421; Observations of Jupiter's Fifth Satellite, Prof. J. M. Schaeberle, 566; the Spectroscopic Binary α Geminorum, A. Belopolsky, 352; Prizes in Astronomy, 373; Double-Star Measures, 373; Lunar Photographs, Camille Flammarion, 373; Periodical Comets, 401; the Rotation of Venus, Percival Lowell, 421; Death of Wilhelm Döllen, 443; Drawings of Mercury, Percival Lowell, 447; the Planet Mercury, Percival Lowell, 617; Prominence Photography, 447; the Chemistry of the Stars, 447; Iron Lines in Hottest Stars, J. Norman Lockyer, F.R.S., 452; Coudé Mountings for Reflecting Telescopes, 472; Three Brilliant Stellar Systems, Prof. T. J. J. See, 498; Double-Star Measures, 516; Belgian Observatory Annual, 516; Bis an's Ende der Welt! Astronomische Causerien, Prof. F. J. Studnička, 532; Mr. Isaac Roberts on Long Exposure Photographs, 544; Vanadium in Scandinavian Rutile, Prof. B. Hasselberg, 544; Columbia University Observatory's Publications, 544; Prof. Harold Jacoby on the Reduction of Stellar Photographs and on the Permanence of the Rutherfurd Photographic Plates, 544; Relationship between the Masses and Distances of the Four Outer Planets, G. E. Sutcliffe, 559; Harvard College Observatory Report, Prof. E. C. Pickering, 566; the International Unification of Time, 567; a Meteorite from New Mexico, Warren M. Foote, 572; a Study of the Sky. Herbert A. Howe, 580; Reflector and Portrait Lens in Celestial Photography, Dr. Max Wolf, 582; Death of Dr. Edward von Haerdtl, 589; Obituary Notice of, 592; Refraction and the Apparent Diurnal Movements of Stars, Dr. A. A. Rambaut, 592; Astronomy: Charles Pritchard, F.R.S., Late Savilian Professor of Astronomy in the University of Oxford; Memoirs of his Life, Ada Pritchard. 601; Peculiar Stellar Spectra, 616; Nova Aurigæ, Prof. W. W. Campbell, 617

Astrophysics: Relative Temperature in Geissler Tubes, R. W. Wood, 274; the Astrophysical Journal, 110

Atlantic, Northern, Deep-Sea Fishes of the, 559

Atmosphère, Les Gaz de l', M. H. Henriet, 533

Atmosphere, the Gases of the, William Ramsay, F.R.S., 435

Atmospheric Absorption of Light, the, W. E. Plummer, 235

Attraction, Central, Lecture-room Demonstration of the Orbits of Bodies under the Action of a, R. W. Wood, 620

Aurora Borealis, the, Alfred Angot, 173

Austen (Prof. Peter T.), Notes for Chemical Students, 77

Australasia: Sir William Macgregor's Recent Journey across New Guinea, and Re-ascent of Mount Victoria, J. P. Thompson, 157

Australia: Western Australia Government Observatory, 183; the Horn Expedition to Central, 581; in the Australian Bush and on the Coast of the Coral Seas, Prof. Richard Semon, W. Saville-Kent, 227; Glaciation in, Rev. J. M. Curran, 240; the Australian Snow Country, John Kummer, 301

Austro-Hungarian Map of Franz Josef Land, the, Prof. Ralph Copeland, 29; Arthur Montefiore Brice, 52

Autobiographical Sketch of James Croll, J. C. Irons, 362

Axe-heads as Currency, Dr. A. Götze, 591

Ayrton (Prof.), Sixty Years of Submarine Telegraphy, 403

Babylonian Tablets, &c., Cuneiform Texts from, in the British Museum, L. W. King, 243

Bacteriology: the Geological Work of Bacteria, Dr. B. Renault, 40; Death of Dr. R. Kerry, 81; Bacterial Water Purification, Mrs. Percy Frankland, 163; Influenza Bacilli in Central Nervous System, A. Pfuhl and K. Walter, 182; Capacity of Bacillus Radicicola of growing on Foreign Culture Media, Messrs. Stutzer, Barri and Maul, 206; the Bacteria which we breathe, eat, and drink, Dr. A. A. Kanthack, 209; the Vitality of Cholera Vibrios, Herr Wernicke, 233; Is Animal Life possible in the absence of Bacteria? G. Nuttall and H. Thierfelder, 238; the Oyster Question, Prof. W. A. Herdman, F.R.S., 293; Oysters and Copper, W. F. Lowe, 366, 415; Prof. W. A. Herdman, F.R.S., 366; Diphtheria Bacilli in Milk, Prof. Schottelius, 301; a Text-book of Bacteriology, E. M. Crookshank, Dr. A. A. Kanthack, 313; Behaviour of Bacteria towards Chemical Reagents, T. Paul and B. Krönig, 328; the Plague Bacillus, Dr. Roux, 370; Dr. Yersin and Plague Virus, Mrs. Percy Frankland, 378; the Bacillus of Yellow Fever, Dr. G. Sanarelli, 370; Papilionaceous Plants and Nitragen, 399; Prof. W. Somerville, 399; Influence of Diet and Starvation on effects of certain Microbial Toxines, J. Teissier and L. Guinard, 408; Applied Bacteriology, T. H. Permain, C. G. Moore, Dr. A. A. Kanthack, 413; Bacteria, Algæ and Free Nitrogen, P. S. Kossovich, 428; Bacteria of the Sputa and Cryptogamic Flora of the Mouth, Filandro Vincentini, Dr. E. Klein, F.R.S., 437; Dr. Koch's Reports on Rinderpest, 450; the James Forrest Lecture, Dr. G. Sims Woodhead, 517; Death of Dr. de Marbaix, 562; Koch's Recent Researches on Tuberculin, Dr. G. Sims Woodhead, 567; Action of Currents of High Frequency on Virulence of Streptococcus, Louis Dubois, 576; Widal's Bacteriological Diagnosis of Typhoid Fever, 590

Baghot-De La Bere (Kinard B.), the New Poultry Guide for British Farmers and others, 485

Bahnson (Kristian), Death of, 276

Bailey (G. H.), the Tutorial Chemistry, Part I., Non-Metals, 195; First Stage Inorganic Chemistry, 532

Baillaud (M. B.), Cours d'Astronomie, 339

Baillie-Grohman (W. A.), Sport in the Alps in the Past and Present, 102

Baker (Bethune), Yellow Butterfly-catching Spider from Orotava, 142

Baker (J. L.), Action of Diastase on Starch, 358

Baker (R. T.), Manna on Blue Grass, 383

Baldwin (Prof. J. Mark), Organic Selection, 558

Balfour (Arthur J.) on Science and Industry, 85

Balfour (Henry), Ancient Assyrian Bow found in Egypt, 71

Ball (J.), Influence of Dissolved Metallic Salts on rate of Solution of Zinc in Dilute Acids, 166

Ball (Sir Robert, F.R.S.), Elements of Astronomy, 28

Ballard (Dr. Edward), Death and Obituary Notice of, 299

Ballistics: the Measurement of Pressures in the Bore of Guns, Rev. F. Bashforth, 460

Balmokand, the Priceless Gem, 233

Baly (E. C.), Passage of Electricity through Gases, 309

Bancroft (W. D.), Chemical Potentials of Metals, 110

Banks (Right Hon. Sir Joseph, P.R.S.), Journal of the, during Captain Cook's First Voyage in H.M.S. *Endeavour*, 1768-71, Sir Joseph D. Hooker, 73

Bar-Hebræus (Mâr Gregory John), Maphrian of the East, the Laughable Stories collected by, E. A. Wallis Budge, 98

Baretge (M.), Effects of Oil at Sea, 360

Barfield (T. C.), Model Drawing and Shading from Casts, 52

Barlow (William), a Mechanical Cause of Homogeneity of Structure and Symmetry, 477

Barnes (C. R.), Analytical Keys to the Genera and Species of North American Mosses, 389

Barr (L.), Melting-points of Metals, 110

Barrett (Chas. G.), the Lepidoptera of the British Islands, 222

Barrett (Rosa M.), Cultivation of Woad, 79

Barry (J. Wolfe, F.R.S.), Abstract of the Presidential Address before the Institution of Civil Engineers on November 3, by, 17

Barton (Dr.), Absorption of Electrical Waves along Wires by Terminal Bridge, 70

Barus (C.), Interferential Induction Balance, 406; Excursions of Telephone Diaphragm, 476

Barus (Dr. Carl), the Practical Treatment of Magnets, 614

Bashforth (Rev. F.), the Measurement of Pressures in the Bore of Guns, 460

Basins, Artesian, in North America, Gibb Maitland, 182

Bastin (Dr. E. S.), Death of, 613

Bather (F. A.), the Inheritance of Specific Characters, 29

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

"*To the solid ground*
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

THURSDAY, NOVEMBER 5, 1896.

THE PHILOSOPHY OF NATURAL SCIENCE.

Studien zu Methodenlehre und Erkenntnisskritik. Von Friedrich Dreyer. Pp. viii + 223. (Leipzig: Engelmann, 1895.)

Erkenntnistheoretische Grundzüge der Naturwissenschaften und ihre Beziehungen zum Geistesleben der Gegenwart. Allgemein wissenschaftliche Vorträge. Von Dr. P. Volkmann. Pp. xii + 181. (Leipzig: Teubner, 1896.)

IF we were to examine these two works purely from the standpoint of the critical reviewer, we should probably content ourselves by recommending the busy man of science to pass them by. We might, indeed, justify the sternness of our judgment by illustrating the hopelessly involved style of Herr Dreyer—his page-long footnotes on footnotes, his misinterpretations of mathematical and physical theories, and his obvious, but nowhere justified, bias against Darwinism. We might then pass to Dr. Volkmann and show the vagueness of his definitions, the unphilosophical character of his epistemology, and indicate the danger which arises when loose analogies drawn from natural science are applied to other fields of thought. We might not unreasonably conclude with a sigh over the departing glory of German science. We might moan over the death or old age of the giants of a quarter of a century back, and regret that the strong and clear intellects of young Germany seem drawn rather to military and commercial pursuits than to the service of science. That Germany has become the first military, and is rapidly becoming the first commercial nation, are now familiar ideas; but that these victories have been won at the expense of literature and pure science, is an aspect of evolution which other nations are only just beginning to realise, and Germany herself will only realise last of all. It is a subtle qualitative, not a quantitative change which has been going on since 1870 in German science and literature. Few realise it, but it is none the less a reality. It is, perhaps, as well that leadership in all spheres should not fall to one people. From the historical stand-point accordingly, these two books are of interest, for they are very typical of much work which Germany has of recent years put forth. Their authors fully recognise that there are great problems still unsolved in the philosophical basis of the natural sciences, but it cannot be said that they throw any light on the solution of these problems, nay, that they even assist us in their clear enunciation. Herr Dreyer indeed tells us with much truth that:

"Auf dem Gebiete der Biologie sieht es noch recht wild und windig aus";

but his lengthy defence of "vital force" is hardly calculated to bring more system into biological thought.

Prof. Volkmann is evidently not quite at his ease in his endeavours to define such fundamental concepts as "natural law" and "physical hypothesis." Yet for him natural laws like the law of gravitation lie outside us while the conclusions of mathematics are thought-laws which lie inside us:

"Diese Naturnothwendigkeiten ausser uns nirgends in Widerspruch treten mit den Denknothwendigkeiten in uns."

This arises apparently from a pre-established harmony the source of which is accounted for in a manner which the writer tells us is the "Kernpunkt meiner erkenntnistheoretischen Studien auf naturwissenschaftlichem Boden." It lies namely in this:

"dass die Logik in uns ihren Ursprung in dem gesetzmässigen Geschehen der Dinge ausser uns hat, dass die äussere Nothwendigkeit des Naturgeschehens unsere erste und recht eigentliche Lehrmeisterin ist."

We are only given this sentence, without *one* word more description of the process by which such harmony has been established! A poet might have thrown out the idea, but put thus in a scientific treatise it is hardly calculated to help us in clearing up our fundamental notions.

It would, however, be wrong to merely smile over what we feel compelled to term trivialities, or to think that they are solely characteristic of German naturalists. A very superficial study of current English physical and dynamical text-books will suffice to demonstrate how much we ourselves need a thorough *Aufklärung* in our

fundamental physical ideas. A mere perusal of current discussions on variation, correlation, panmixia, will avail to show how "right wild and windy" it is in the field of English biology also. This is the second stand-point from which a consideration of the ideas of Dreyer and Volkmann may be of value. Their books may help us to realise the condition of affairs at home, and if we do that we shall hardly find much ground for national self-congratulation.

During the last ten or fifteen years a very great revolution has been more or less silently taking place in the philosophical theory of men of science. The revolution is very far from being complete, for old theories are hard to dissolve when they have crystallised into dogmas. The chaotic definitions of the text-books, the chaotic thinking of too many biological controversialists, are all signs of a transition period, of new ideas struggling with old modes of expression, with an antique terminology suited to a scientific philosophy no longer capable of satisfying modern intellectual needs. But whether we turn to Germany, to France, or to our own country, and study the literature which touches on the *erkenntnis-theoretische* foundations of science, we shall alike be forced to the conclusion that a revolution in scientific thought has been taking place, and that in the minds of the more philosophical men of science, it is already complete. There are many ways of summing up the purport of this revolution. Perhaps the shortest, if not the most expressive, is to say that the old division of science into exact and descriptive sciences is now seen to be illusory. The immense progress made in the first half of this century with theoretical mechanics, the success with which mechanical reasoning was applied in the third quarter of the century to the great physical discoveries of that period, led men of science not unnaturally to postulate mechanism as the basis of all natural processes whatsoever. Particles, molecules, atoms, impacts, vibrations, laws of forces were the forms under which all nature worked, and by which all things were to be *explained*. The dogma that mechanism would explain the universe may have been philosophically absurd, but by concentrating men's thoughts on one method of investigation, it led to a whole round of splendid discoveries. For all but the great leaders of science work under any theory, under any dogma indeed, which has produced and is still capable of producing great results, is far better than the invention of new hypotheses. Fruitful new hypotheses have almost always been the product of master-minds, which have worked out old theories to the point at which they are seen to absolutely contradict phenomena. The 'prentice hand finding some new fact at present unaccounted for by the old-established theory is generally over-hasty with the fabrication of a new hypothesis. The true criterion for the modification or rejection of an established theory which has produced sound scientific results is not its present insufficiency to account for this or that isolated group of phenomena—its insufficiency may arise from the weakness of our analysis, or from want of insight in our application of it—the criterion lies rather in a demonstrable contradiction between the theory and some particular class of phenomena. The existence of such a contradiction can only be satisfactorily proven by a master with the firmest grasp of theory and the fullest appreciation of natural facts. Had the necessity for such a criterion been borne in mind, the field of biology would possibly not now look so "wild and windy." Has there not been a far too ready invention of new hypotheses—on the ground that the theory of natural selection combined with heredity has not hitherto provided a satisfactory account of certain phenomena—while, as a matter of fact, the modification or rejection of such a fruitful theory ought to be solely based on the absolute contradiction of its deductions by our experience of nature?

The whole point is, indeed, well illustrated by Herr Dreyer's onslaught on "die moderne Entwicklungslehre mit ihrem famosen Darwinismus," which "noch so kannibalisch wohl fühlt." It is perfectly easy to show that neither Darwinism[1] nor mechanism in their respective spheres have accounted for anything but a small fringe of organic phenomena. It is quite easy to postulate the possibility of other evolutionary hypotheses and of "vital forces," which in the future may render account of other ranges of phenomena. But take, for example, such a concept as "vital force"—the definition of which is so obscure that it is impossible to assert or deny its existence—and ask what fruitful results it has contributed to biology as compared with what has been achieved by an application of mechanical theory—under which term we should include chemico-physical laws? Herr Dreyer is very stern with Otto Liebmann for ridiculing "vital force"; but when we come to investigate what Herr Dreyer himself understands by "vital force," it appears to be embraced in a *Lebensgesetzlichkeit*, which shall be coordinate with, and not superior to the *physikalische Gesetzlichkeit*. The study of this *Lebensgesetzlichkeit* is to form the science of *Vitalistik*. It would be interesting to know who has been so rash as to deny the existence of yet undiscovered laws of life, which are not identical, but coordinate with already established physical laws. Herr Dreyer's position may be thus summed up: It is not proven that physics can lead us everywhere in the organic field, let us try the fabrication of new hypotheses and build up a new science of vitalistics.

Well, and good! A master-mind may some day propound an hypothesis of value; we should have preferred the statement of single new *Lebensgesetz* to all Herr Dreyer's discussion on *Lebensgesetzlichkeit*. We hold that for the every-day man of science it is better to work a by-no-means exhausted vein of ore, than rush off to the still unworked, but highly-puffed field of vitalistics. Science as well as commerce has its gold reefs—without gold. Nor was the attack of the *so kannibalisch wohl fühlende moderne Entwicklungsmänner* on *Lebenskraft* without its justification. That term embraced an unscientific attempt to slur over ignorance, and encouraged loose thinking by stealing from mechanics in the word "force" some of the clearness and definiteness of mechanical concepts. That no knowledge of *Lebensgesetzlichkeit* came out of its use, can we think be historically proven, nor are we, indeed, prepared to admit that it even acted for a time as a successful bulwark against a materialistic view of

[1] By "Darwinism" may here be broadly understood the theory which supposes evolution to have taken place by natural selection combined with heredity.

life. The materialistic view of life—the theory which would *explain* all organic and inorganic nature by force and matter—has disappeared owing to a wider and more philosophic view of mechanism, and not to the logic of vitalists. It is the physicists, and not the biologists, who have broken down the barrier between the exact and descriptive sciences, and among whom a truer view of mechanism has arisen. The biologists have been only too ready to offer "explanations" of various organic processes by appeal to molecules, centres of force and energies. While they have been attempting a mechanical basis for descriptive science, the physicists have learnt that mechanics, after all, is but a descriptive science itself. "The object of mechanics is to *describe* in the simplest possible fashion the motions which occur in nature." Such was Kirchhoff's definition, and the acceptance of that definition is really the revolution which has been going on in natural science. It is a revolution which cuts at the idea of force as a cause, but sees in it only a measure of change; it is a revolution which thrusts upon us the agnostic position of watching and describing, and which drops *explanation* out of the scientific glossary or defines its old sense entirely away. It is a revolution which again renders for us the motion of a planet every whit as mysterious as the oscillations of protoplasm. We can explain neither, although long study and observation have enabled us to describe one motion in much simpler terms than the other.

Mechanism as the description in the simplest possible terms, not the explanation, of natural motions is a revolutionary definition which at once reduces all physics, chemistry and biology to the same simple footing. In all three sciences it is the sequence of changes in space and time that we endeavour to describe in the simplest language. In doing this, we are inevitably thrown back on geometry and kinematics. The conceptions of these sciences are not identical with real experience; they are based on ideal forms and ideal ratios drawn as limits from our experience of phenomena. But it is in terms of these only that we succeed in describing change, and this geometrical and kinematic description of change, and of repeated sequences of change is what we are to understand by mechanism in its broadest sense. It is this mechanism, which embraces such inventions of the intellect as particles, molecules, atoms and ethers, and describes kinematically, or in terms of the motions it attributes to them, physical phenomena. Organic phenomena may require to be described by other conceptual elements having other modes of motion attributed to them than those which have hitherto been adopted in physical descriptions. But if organic phenomena are to be described scientifically, it must be by a series of symbolic forms moving in time and space. In this sense biology must ultimately become a mechanical science. This does not mean that life can be "explained" by mechanism—on the contrary, mechanism explains nothing, not even physical nature—but that the bulk of natural science is a description of change, of motion in time and space, and that the invention of comprehensive and brief formulæ of motion is the function of mechanics. In this sense it seems impossible to contrast mechanism and "vital force," or to maintain any rigid line of demarcation between the physical and descriptive sciences.

From this standpoint, which we believe to be the firm ground, soon to be left behind by the sea of current *erkenntnistheoretische* controversies, how purely idle does Prof. Volkmann's disquisition on natural laws, rules, hypotheses, and axioms appear! Thus Newton's law of gravitation, the principle of energy, Galilei's law of inertia, he tells us, are *Naturgesetze;* Kepler's laws of planetary motion are merely *Regeln*, and the undulatory theory of light an *Hypothese!* Yet Prof. Volkmann's definitions are worth noticing, because they show us so very clearly the present transitional state of scientific thought.

"Das Naturgesetz bildet den kürzesten und zugleich reichhaltigsten Ausdruck für das, was thatsächlich geschieht und zwar was ausnahmslos geschieht, was geschehen muss" (p. 58).

It is the *sinnliche Wahrnehmung* which changes the *Hypothese* to the *Naturgesetz*. But we must ask, what physicist ever caught a particle, or had a *sinnliche Wahrnehmung* of how two particles, if caught, would attract each other? How is Newton's particle more real than the atom of the chemist? Even Dr. Volkmann admits that the conception of the atom as something *bildlich symbolisch*, is to-day winning ground everywhere. How can we have *sinnliche Wahrnehmung* of the law of inertia? Does it not require the most ideal conceptions of relative motion and of "fixed axes" to at all realise its meaning; and is it then more than a definition of acceleration? We cannot find this law *so einleuchtend* and *so unmittelbar* as Dr. Volkmann believes, nor consider that its essence can be scientifically illustrated by the motion of a locomotive over smooth rails, when the steam is cut off. Indeed our author skates somewhat lightly over the abysmal gulf of the relativity of all motion. He has given up force as a reality, but the influence of relativity on all forms of kinetic energy does not appear to have struck him, and, like many another physicist, he would probably suppose we had some *sinnliche Wahrnehmung* of the absolute in a quantum of energy. The undulatory theory of light was purely hypothesis so long as it was *übersinnliche Anschauung und Vorstellung;* but now that the young German physicist Wiener has photographed light waves, we are told, that it has ceased to be an hypothesis, it has become *eine vollendete Thatsache!*—a law of nature. In not one of such natural laws, however, is there anything of the *muss* of Prof. Volkmann's definition. They are purely *bildlich symbolisch* descriptions of motion, more or less simple, more or less complete and satisfactory.

The reader will notice at once how far many students of science are yet from using the language and appreciating the ideas involved in Kirchhoff's definition of mechanism. Mechanism, whether it be that of the particle, the atom, the ether, or the cell, is a description of motion in the simplest terms the mind can invent, and this description is always in terms of those *bildlich symbolische* elements, which we construct from such ideal sciences as geometry and kinematics. We may attach constants to these elements to be determined by experience, and to be termed charges, masses, &c., and, perhaps, in the distant future, when the science of vitalistics is complete, vital units; but the elements none the less remain *bildlich symbolisch*. They are mental constructs, by which the scientific mind

endeavours to describe its past and predict its future experience in the briefest possible terms. It is this creation of *Naturgesetze* by the mind, this invention of brief formulæ, which is at once the glory and limitation of science. The mind does not explain for us what the world of *Dinge an sich*, which we term nature, may be in and for itself; it seeks with all its ingenuity to describe *bildlich symbolisch*, what falls within the limits of its experience. The progress of science lies in the increasing comprehensiveness and brevity of its descriptions.

Prof. Volkmann tells us that:

"So lange die Naturwissenschaften mit einem inneren Verhältnis zwischen Geist und Natur arbeiteten, war ihr Fortschritt gehemmt" (p. 123).

If this were true, then must natural science and the discovery, or rather *invention* of natural law be for ever retarded, for science must always work at this very relation between mind and nature. It is, however, not the right but the wrong appreciation of the relation of mind to nature which checks scientific progress. The completion of the revolution we have hinted at in this review, so far from being detrimental to natural science, will go a long way towards freeing its workers from the attacks which have been made upon science from more than one quarter, and which have largely arisen from a confusion of the idea of mechanism with some form of materialistic theory. Released from the need of replying to external criticism and attack, science will have the more energy and leisure to progress quietly in its own proper field.

KARL PEARSON.

OUR BOOK SHELF.

Text-Book of Comparative Anatomy. By Dr. Arnold Lang. Translated into English by Henry M. and Matilda Bernard. Part ii. (London: Macmillan and Co., Ltd., 1896.)

THIS volume of Dr. Lang's text-book treats of the Mollusca, Echinodermata, and Enteropneusta. To the first group of animals 283 pages are devoted, and to the latter two 319. The complete and systematic manner in which the structure and relations of the different families and orders described in this work are dealt with, renders each of the three chapters, into which the book is divided, a valuable monograph. Regarding the phylogeny of the Enteropneusta, Dr. Lang states that they "are not closely related to any single large division of the animal kingdom"; his treatment of them in this volume is sufficient evidence that he is not inclined to attach much weight to their supposed affinities with the Chordata. In a short notice it is quite impossible to give any idea of the interesting way in which the book is written. The English translation is all that could be desired; the illustrations are excellent. The arrangement of the subject-matter has been carefully thought out, and reference to any subject is assisted by the use of different kinds of type in the text. A long classified list of the important literature is given at the end of each chapter.

Experience: a Chapter of Prolegomena. By the Rev. Wilfrid Richmond. Pp. iv + 64. (London: Swan Sonnenschein and Co., Ltd., 1896.)

ACCORDING to the author, the initial obstacle to the progress of philosophy is the doctrine that experience cannot give the knowledge of reality—that nothing can be definitely known. This view he demolishes by showing that reality is actually to be found within the field of experience, whence the sensible conclusion is arrived at that "experience is the beginning and end of philosophy."

Islandic Earthquake Recorded at Paris.

LE No. de NATURE du 15 octobre contient une note très intéressante de Dr. J. Stefansson, sur le tremblement de terre survenu en Islande le 26 août dernier.

J'ai l'honneur de vous informer que les courbes relevées, à cette date, au magnétographe de l'Observatoire du Parc Saint-Maur, portent nettement la trace de trois troubles particuliers, paraissant se rattacher à ce phénomène. Le premier s'est produit à 11h. 36m., et les deux autres, qui sont plus accentués, respectivement à 11h. 42m. et 11h. 46m. du soir, temps moyen de Paris. TH. MOUREAUX.

Observatoire du Parc Saint-Maur, le 29 octobre.

Earth Tremors at Edinburgh between August 25 and September 6.

IN connection with Dr. J. Stefansson's article in NATURE of October 15, on the "Recent Earthquakes in Iceland," it may be of some interest to note that the photo-recording bifilar pendulum, presented to this Observatory by M. d'Abbadie, and placed under my care by Prof. Copeland, exhibits on the dates given by Dr. Stefansson several strongly marked irregularities in the curve, which may possibly have had their origin in the Icelandic disturbances. The following table contains a list of all the pendulum oscillations recorded on the photographs between August 25 and September 6, with the Greenwich Mean Times of their occurrence.

	Earthquakes in Iceland.	Edinburgh pendulum oscillations. Begin.	Edinburgh pendulum oscillations. End.	Tilt of pendulum frame.	
				″	
Aug. 25		9.25 a.m.	?	0·4	Slight.
,,		4.45 p.m.	5.50 p.m.	0·6	Slight.
26		9.10 a.m.	11.5 a.m.	0·4	Very slight.
,,		0.55 p.m.	2.10 p.m.	1·0	Slight, but well-marked.
,,	10.30 p.m.	11.10 p.m.	11.30 p.m.	About 2	Gap.
27		6.35 a.m.	?	1·25	Well-marked.
,,	9.15 a.m.	10.50 a.m.	11.5 a.m.	About 2	Gap.
,,		4.10 p.m.	5.40 p.m.	0·5	Very slight.
29		11.20 a.m.			Several almost imperceptible tremors at irregular intervals.
30			4.30 p.m.		
30		4.30 p.m.			No trace of disturbance, but record not complete.
Sept. 4			4.50 p.m.		
4		4.50 p.m.			Photographic trace a perfectly straight line.
6			0.5 a.m.		
5–6	11.30 p.m.	0.5 a.m.	0.20 a.m.	2 to 3	Gap
6	2 a.m.	No disturbance here.			
,,		9.5 a.m.	?	1·0	Well-marked oscillation.

The points of special interest in this table are the three violent oscillations which have been designated gaps. These are complete interruptions in the curve, caused apparently by successive waves of sufficient amplitude to produce so rapid an oscillatory motion of the pendulum, that the reflected ray traverses the exposing slit too quickly to leave any photographic trace. The result as seen on the photograph is an abrupt termination to the curve line; then for a period of from five to ten minutes no photographic effect whatever is produced, and for about a similar period, a widened and badly defined trace shows that the ray has oscillated to each side of its normal position, with an amplitude of disturbance at the time when the trace begins to reappear of fully 2″, but which must have been considerably greater at the beginning of the gap, where the record is altogether wanting. After this the mirror comes to rest, and the ordinary trace reappears.

In the case of all the smaller irregularities of the curve, the ray seems to have moved more or less abruptly to a distance from its normal position, after which the mirror gradually settles to rest. Careful measurements give, for the arc through

which the pendulum frame is tilted, the numbers contained in column 5.

Unfortunately, between August 30 and September 4, the record is incomplete, some fifty hours having been lost by the photographic paper repeatedly running so much to one side as to stop the clock. This difficulty, it is hoped, has now been overcome. THOMAS HEATH.

Royal Observatory, Edinburgh, October 26.

Whirlwind on "Rydal Water."

SOME friends and myself were staying at Lowwood Hotel, Windermere, for a few days, and on Friday, October 16, we were walking by "Rydal Water," on the opposite side from the road, when we noticed a very curious and most unusual effect on the water, caused by a sudden very heavy squall of wind, which seemed to come from two directions at one time, creating a "whirlwind," and raising the water and spray on the lake fully 100 feet high or more. There were eight or ten of these disturbances during the time we stayed (probably about twenty minutes), and I was fortunate enough to have my hand-camera with me and to photograph the largest of them, which came sweeping down the lake towards the island (near the centre), and finally broke on the shore with a boom like a cannon, which threw the débris, &c., at the side into the air quite 40 feet high. I have seen small whirlwinds strike on various lakes, but never anything of the magnitude of this. Thinking the incident might be of interest to you, I send you a photograph to make what use of you like.

Whirlwind on "Rydal Water," and smaller one in distance, October 16.

Had a small boat or ordinary Windermere yacht been caught in one of these whirlwinds, she must have been swamped.

HENRY J. C. ANDERSON.

Rodono, Great Crosby, near Liverpool, October.

The "G" Section of the British Association.

PERHAPS I may be allowed to make a few remarks concerning the above Section, and the strictures passed on October 22 upon its work, by the writer of the report in your columns. The writer is not singular in his criticisms, for others representing the scientific and practical sides of engineering also speak from time to time in a disparaging way, both of the subjects themselves, which are dealt with under the head of Mechanical Science at these annual gatherings, and of the methods of dealing with them.

I am not in any way concerned in defending the present state of things, but I would point out that no one yet seems to have suggested any really better general plan of carrying on the business of the Section. The writer in your columns indicates, for instance, that the week should be devoted to discussions such as that upon the fracture of railway rails, or the report on tidal influences. While admitting the value of these two communications, and others of a similar kind, there appear to be serious objections to limiting the work of the Section entirely to such matters, which work, I venture to think, your reporter entirely mistakes in its relation to technical societies. These societies, such as the Institutions of Mechanical Engineers, of Naval Architects, of Electrical Engineers, of Mining Engineers, and the Iron and Steel Institute, specialise their work, and deal often in a different way with quite different subjects. Now the British Association affords a common meeting ground for all interested in these and other branches of applied science, and, indeed, for many who may not have any special knowledge of any branch at all. Hence papers, or even lectures, upon which discussion is admitted and invited, dealing with dock works (which surely it is quibbling to exclude from the range of mechanical science), electric railways, the Tower Bridge, waterworks, not to say of armour and ordnance, of wreck-raising, of motor carriages, &c.—in all of which an account was given of progress in applied science—seem to form an important part of the work of the Section. Indeed, those authors who took the trouble to prepare illustrations, lantern slides, and models to make their subject clear and interesting, or even, if you like, "popular," deserve the hearty thanks of those present.

It might perhaps be a good thing to make some division in the day, so that the scientific papers and discussions which, to be frank, frequently empty the room, might be taken early before a certain hour, after which papers of a more popular character might be announced for reading and discussion.

As for trade articles, it might be fairly argued that new inventions not coming under that head—even scientific instruments, for example—have generally no value or interest at all; and the Committee of the Section seem always to try and ascertain, before accepting a communication of this sort, if there is sufficient novelty and scientific interest to warrant its acceptance; and in this matter, the "morality" of the Section need not be higher than that of technical societies. Indeed, if advertisement were a ban to acceptance, a good many of the authors themselves at most of the Sections would be hopelessly rejected. The "touting circular" referred to, if indeed it can be called such, was given out by one of the secretaries to only a portion of the meeting, and the remaining copies withheld when his attention was called to the contents. It is scarcely right to intimate that this sort of thing ever occurs except as a rare accident.

H. S. HELE-SHAW.

Walker Engineering Laboratories, University College, Liverpool, October 26.

P.S.—Mr. Johnson, of Derby, is mentioned in mistake for Mr. R. E. Johnston, Engineer of the Joint London and North-Western and Great Western Railways.

Suggested Reef Boring at the Bermuda Islands.

THE issue of NATURE containing the notice of the failure of the Royal Society boring expedition has just reached me, so I hasten to call attention to the great value of the Bermudas as a permanent home for a scientific station, and where borings might be readily conducted at any convenient time. A glance at the map will show that the fauna of the deep sea, of coral reefs, the avifauna of the ocean, and a complex meteorology, may all be studied at one and the same station, and in close proximity to New York and Halifax.

Could the Smithsonian Institution or the Royal Society be induced to take the matter up, it would seem to be an easy matter to organise a station, as the funds required are not large.

The town of St. George's very probably would give a dock with house attached, and possibly the colony a small sum annually. If the Universities of America would take an interest in the matter, the enterprise might be immediately pushed along.

I should like to see in NATURE the views of some scientific men on this matter, both of Britain and America.

The question is certainly of great importance to scientific inquirers in nearly all branches of scientific endeavour, and it is to be hoped abler minds than mine may lay hold of the enterprise. W. K. MORRISON.

Devonshire, Bermuda Islands, October 15.

Siemens' Domestic Gas Fire.

DR. POLE'S letter on the Siemens' Domestic Fire drew my attention to the inquiry on the subject which Mr. Foster addressed to you in his letter published in NATURE of September 17.

I have had one of these fires in my office at the Society of Arts for some years. It was put in under Sir William Siemens' own superintendence, about the time when he described the grate in NATURE, so it must have been at the end of 1880 or the beginning of 1881. For a long time I used it with coke in the manner intended by the inventor; but practically I have found it more convenient to use ordinary coal, although it is doubtless less economical.

As Dr. Pole points out, the convenience of having gas ready to be turned on whenever the fire gets low or goes out, is very great; and in cases where a rather wasteful consumption of gas can be prevented, or is not considered of great importance, there can be no doubt but that the fitting of a few gas jets to an ordinary grate is a very great convenience. There is also a good deal of trouble saved in the lighting of the fire, as no paper or wood is required: the grate is simply filled with coal, and the gas turned on and lighted. The fire, I should say, burns up at least as rapidly as when lighted in the ordinary way.

If any of your readers are interested in the question, they are very welcome to see the grate at work whenever they like to call here. H. T. WOOD.

Society of Arts, John Street, Adelphi, London, W.C., November 2.

Diselectrification by Phosphorus.

IN the course of some experiments made a few weeks ago, upon the discharge of electricity by air which had been traversed by X-rays, it occurred to me to try whether similar action would be exerted by air in which phosphorus was being oxidised. I found that a gold-leaf (Dutch metal) electroscope was quickly discharged when a stick of phosphorus was held near it. A small metal crucible was afterwards connected with the electroscope, and a clean slice of phosphorus half an inch in diameter was supported within it at a distance of about half an inch from its sides and bottom. The electroscope was completely discharged in six seconds, the action being more rapid than that of a burning strip of nitrate of lead touch-paper one inch in width.

It might be found convenient to attach a lump of phosphorus instead of a fuse to the nozzle of a water-dropping collector in times of severe frost.

I do not remember to have met with a previous record of this observation. It is of interest in connection with the note on slow oxidation, in NATURE of October 29 (p. 631).

SHELFORD BIDWELL.

The Departure of Swallows.

"E. P." mentions in NATURE of October 22, a date, somewhere about October 20, I presume, which he considers is an unusual one for swallows. Now, though the bulk of the swallows have left by this time, it is by no means unusual to see them later on in the year. In 1894 I saw swallows in Kent, in the neighbourhood of Tonbridge, on October 20, 21, 25 and 27, and the last one on November 11; it was flitting about a village in a bewildered sort of way, with a crowd of village boys throwing mud and clods of earth at it.

The same year a flock of martins stayed near some buildings from October 28 to November 16; by this time many of them had died of cold.

The latest swallows I have seen this year I saw on October 23, near the same buildings. J. BROWN.

Tonbridge, Kent.

I BEG to send you the following extracts from my journal respecting the late appearance of the swallows.

1855, December.—It is worthy of record that several swallows were seen in this locality towards the end of November and during the first week of this month. I have ascertained that they were seen in other counties at the end of November; it must not be considered, therefore, as a merely local or solitary instance of the late appearance of these birds.

1863, October.—A few swallows were seen flying above the church on the 24th, and again on the 31st.

1867, November.—Some swallows were observed flying about during the last week.

These observations were made at Uckfield.

C. LEESON PRINCE.

The Observatory, Crowborough Hill, Sussex, October 26.

A Mechanical Problem.

THE mechanical problem proposed by your correspondent, "Cromerite," in the last issue of NATURE (October 29), is practically answered by the so-called "jumping beans" that are now being exhibited and sold in many parts of London. In this case a hard, rigid seed is seen to travel about in a series of small jerks, being slightly lifted from the ground at each movement. Upon dissection the seed is found to be hollow, the original contents having been devoured by a coleopterous larva—a soft fleshy maggot—which now partially occupies the cavity, and by its spasmodic movements causes the strange antics of the natural box in which it is enclosed. The walls of the seed appear to be quite rigid and inelastic. E. E. GREEN.

November 1.

HERTZ'S MISCELLANEOUS PAPERS.[1]

ANYTHING written by Hertz is of interest; and these papers are of interest, not only on this account, but also on account of their suggestiveness. It is always a question as to the desirability of republishing and translating papers published some years ago. Most valuable papers of ten years' standing have produced their effect. Their vitality has been transmitted to and reproduced in subsequent work, but what the scientific world requires is advance rather than revision. The work of pioneers is, however, largely an exception to this rule. They are generally in advance of their times, and much of their work is of value long after it was done. Such an one was Hertz. Most of his papers are suggestive of questions which still require answers, and they all breathe a spirit that, as he says himself of Helmholtz's work, evokes "the same elevation and wonder as in beholding a pure work of art." His papers are not mere enumerations of observations, nor mathematical gymnastics. Each has a definite purpose and an artistic unity. A life-giving idea pervades it. It is no mere dry bones, but an organic whole that lives for a purpose, and does some work for science.

Prof. Lenard has earned much gratitude for his Introduction. It gives a charming picture of Hertz, of his simplicity, his devotion to science, his loving regard for his parents. There is just enough added to the very well-selected letters to give the reader a continuous view of Hertz's work, and enable him to follow its development, and hence feel an interest in it and sympathy with the worker, thus fulfilling the best ideal of the biographer.

One of Hertz's first investigations was as to the kinetic energy of an electric current. The question is still of great interest. It is known that the magnetic induction that accompanies an electric current behaves exactly as if it were a mass moving with inertia. This is the inertia of magnetic induction. Hertz was, however, looking for a different inertia. He looked at the subject from the flow of electricity point of view. He thought that there might be some phenomenon corresponding to an inertia of the electric charges, which upon this theory are supposed to be flowing in opposite directions through a conductor. He supposed that these might have some inertia

[1] "Miscellaneous Papers." By Heinrich Hertz. With an Introduction by Prof. Philipp Lenard. Translated by D. E. Jones and G. A. Schott. Pp. 364. (London and New York: Macmillan and Co., Ltd. 1896.

in addition to the magnetic inertia which accompanied their motion. To test this he tried two different forms of experiment, and obtained results which showed that if there were inertia of this kind, it must be small compared with that of the magnetic kind. The first method consisted essentially in a careful comparison of the extra current in a conductor with its calculated value; the second consisted in observing whether anything like the action by which the trade winds are deflected from a due northerly and southerly flow by the rotation of the earth, could be observed in a rotating conductor when traversed by an electric current. That there is some directed inertia in the conductor when traversed by an electric current is very probable, and in some cases we can be sure it exists. Hertz himself remarks that the inertia of the motion of the ions in electrolysis is considerably greater than what he was looking for in a metallic conductor. He could not make sufficiently delicate experiments with his apparatus to detect it, however, when using the small densities of current that were available in liquids; but the question is of great interest, and deserves further investigation. There can be no doubt that in gaseous discharges, kathode rays, as well as in electrolysis of liquids, there is a directed motion of matter accompanying the electric current which would be of the nature of the inertia Hertz was looking for, but failed to find. There seems much reason for thinking that in metallic conductors some similar actions are also taking place. Besides all this, there is the question as to how far the theory that all electricity is molecular and consists of electrons, involves the supposition of an inertia of this kind. Is the inertia of an electron completely specified by the magnetic force accompanying it? Does it occupy no space itself, and is its external field its all? We are hardly in a position to answer such questions. We might, however, be able to answer the former question as to the inertia of the directed matter movements accompanying the current, and as to another interesting question of a similar kind, namely, as to how far we can legitimately assume the current inside a conductor to be absolutely homogeneous. The self-induction of a single wire of a square m.m. in section is not exactly the same as that of, say, a hundred wires each of the thousandth of a square m.m. in section, and distributed over the square m.m. Subdividing the current would increase its self-induction. Outside the wire the distribution of magnetic force would be practically the same as before, but inside we would have it concentrated into a hundred small wires instead of being uniformly distributed, and the effect of this would be to slightly increase the self-induction, and the more so the smaller the section of each wire into which the square m.m. were subdivided. Hence we conclude that if the current in a real wire be from molecule to molecule, and so be concentrated on certain lines, its inertia should be somewhat greater than that calculated from the hypothesis that it is uniformly distributed over the section of the conductor. The difference between these two views is most clear when we consider the case of a Leyden discharging by its insulating medium becoming a conductor. If the Leyden be completely closed, and the medium become a conductor in such a way that the strain in each cubic cm. is there destroyed by conductivity, there will be no magnetic force anywhere accompanying this discharge of the Leyden, and consequently no magnetic inertia, if the conduction be perfectly homogeneous. Now it seems almost impossible that any directed change can take place without some accompanying inertia, and we may consequently conclude that either (*a*) an electric current has inertia such as Hertz was looking for, or (*b*) electric conduction currents are essentially heterogeneous, or (*c*) electric conduction is essentially accompanied by material inertia, or (*d*) two or all three of these are true. That (*c*) certainly exists in this case is incontestable in view of the known directed strains that Kerr and Duter have proved to exist in matter subject to electric stress. What is the complete answer, is the important question. It is still unsolved. It lies at the foundation of every theory of electric conduction. Hertz attacked it. It is still waiting solution.

The papers on the contact of elastic spheres and on hardness are most valuable contributions to the subject. They place the question of hardness on a scientific basis, and lay the foundation for a quantitative study of this most variable property of matter. There is no quality in which different materials differ more than in hardness. Electric conductivity is perhaps as various as hardness, compressibility, and viscosity, but hardly any other quality of matter is at all comparable with these in variety of range. Of these hardness is one of the most important and least known, and since Hertz's work on it can be scientifically studied. Innumerable subsidiary questions arise in connection with it. Why are some bodies so easily polished? Is the polishing of marble connected with the ease with which crystals of calcspar can be twinned by pushing over one corner? What is the essential difference between polishing and grinding? What is the effect of impurities on hardness? Is it comparable to their effect on electric conductivity? What is the cause of this effect?

In considering the cracking of a material like glass, Hertz seems to think that its cracking will depend only on the tension; that it will crack where the tension exceeds a certain limit. He does not seem to consider whether it might not crack by shearing with hardly any tension. It is doubtful whether a material in which there were sufficient general compression to prevent any tensions at all, would crack. Rocks seem capable of being bent about and distorted to almost any extent without cracking, and this might very well be expected if they were at a sufficient depth under other rocks to prevent their parts being under tension. It is an interesting question whether a piece of glass could be bent without breaking if it were strained at the bottom of a sufficiently deep ocean. On the other hand, there seems very little doubt that the parts of a body might slide past one another under the action of a shear, and would certainly crack unless there were a sufficiently great compressive stress to prevent the crack, and that consequently a body might crack, even though the tensions were not by themselves sufficiently great to cause separation, and might crack where the shear was greatest, and not where the tensions were greatest.

Then follow some papers on hygrometry and evaporation. A very interesting point is raised in this latter connection. Can a liquid evaporate at an unlimited rate if the vapour produced is removed as rapidly as it is evolved? From two points of view Hertz shows that there is a limit, and by his experiments went far to show that there was no other cause limiting the rate of evaporation. The first point of view was that a limit is imposed by the difficulty of supplying heat sufficiently rapidly to keep the surface temperature constant. He does not seem in his experiments to have attempted to supply this by radiation, but was content to allow the liquid to supply itself by conduction and convection from below. The second point of view was that the molecules could not leave the surface faster than they would be moving in the vapour that was formed. Hertz's investigation of this case only assumes an average velocity for the molecules; he does not consider the distribution of velocity among the molecules, nor whether they escape equally easily in all directions. The experimental investigation of the conditions of evaporation is extremely difficult; and until some more satisfactory method of studying these conditions be invented, the rough approximation seems to be sufficient to explain the observations. It might be interesting to see whether there was any difference between

the superficial friction of a gas and a liquid which did not evaporate, and of a vapour in contact with its own liquid. In one case there would be no exchange of molecules between the two bodies that were sliding past one another, while in the second case there would be an exchange. A study of the conduction of heat between a gas and a liquid might also help to elucidate the nature of the exchange which takes place between a liquid and its vapour.

In the paper on the vapour pressure of mercury, there are some very rough approximations which are hardly sufficiently accurate for general application. One is as to the extent to which a saturated vapour obeys the laws of a perfect gas. Hertz assumes that this is more nearly true the lower the temperature. This is not generally so. For each kind of material there is a particular temperature at which its saturated vapour most nearly obeys these laws, and below as well as above this temperature it departs from these laws. Again, there is a process, described at the bottom of p. 203 and top of 204, which cannot possibly be carried out. He says: "Let a quantity of liquid at temperature T be brought to any other temperature. At this temperature it is converted into vapour without external work." This is absolutely impossible, and the equation he deduces from all this is not true, though it is sometimes a rough approximation to the truth.

There is a very interesting paper on the floating of bodies by thin sheets of rigid material like ice. Hertz shows that if the sheet be large enough it would be possible to cause a thin sheet of iron, which by itself would sink, to float by placing weights at its centre. The weights might so depress the centre and make the sheet so boat-shaped as to float both themselves and it.

In 1883 Hertz published a deduction from first principles of Maxwell's equations for the electromagnetic field in the symmetrical form, afterwards used by himself in his investigations on oscillatory discharge waves. He applies the very same arguments by which Helmholtz, Lord Kelvin, and others had argued from the work done by one electric current on another, that there must be a corresponding reaction of the second on the first current, and hence deduced electromagnetic induction. Hertz applies this argument to the case of a ring magnet changing in strength and producing magnetic force on another ring magnet in its neighbourhood, and doing work there, and shows thereby that there should be a magnetic force due to a changing electric field exactly corresponding to the electric force due to a changing magnetic field. This, of course, is what Maxwell describes as the magnetic effect of the changing electric displacement, and its effects are expressed by the very same equations as Maxwell deduces. The argument is no more and no less conclusive than in the corresponding application of the principle of the conservation of energy to deduce ordinary electromagnetic induction. Hertz is careful to point this out, for he was early imbued by Helmholtz with the fact that the principle of the conservation of energy is by itself utterly inadequate as a complete explanation of physical phenomena. He specially mentions himself Helmholtz's interest in this problem of the simplest basis for dynamics, and Hertz's last great work was to place general dynamics on a sound basis. The simplest of all cases is the easiest in which to see how the principle of the conservation of energy fails to give a complete solution. A body moving without any action from other bodies describes a right line at a constant velocity. The principle of the conservation of energy requires the constant velocity. But, why the right line? Conservation of energy cannot solve even the simplest of all examples. It would be well if some modern chemists would mark, learn, and inwardly digest this.

The part of Hertz's work which is of greatest interest just now is that in connection with kathode rays. He began with some very interesting observations on the aura accompanying spark discharges. It appeared to be projected from the positive electrode, and occasionally formed a vortex ring of incandescent gas, which lasted for an appreciable time between the electrodes of a jar discharging in air. Goldstein has noticed similar effects, and some recent experiments on the discharge of large Leyden batteries, in which some of the phenomena of globular lightning seem to have been reproduced, make it appear possible that this latter is a spherical vortex of incandescent air.

Hertz's study of kathode rays in 1883, set finally at rest two questions. In the first place he showed that the discharge in a gas may be as continuous as any other form of current. In no case are we absolutely certain that the current is absolutely continuous. On the large scale it certainly is; but all we know of electrolysis seems to show that on a sufficiently small scale the current is carried in detachments, and is consequently essentially discontinuous. This, however, was not the question at issue, and so far as a continuity of the same kind as that in any liquid electrolyte is concerned, Hertz showed that the discharge through a gas might be equally continuous. The second question he decided was as to the direction of flow of the average current in an exhausted space. He showed that the average flow at any point was nearly the same as if the whole space were a conductor: that there was no connection between the kathode rays and the flow of the current. From experiments on kathode rays projected down a tube, and quite away from both electrodes, he deduced that they produce no magnetic action outside the tube, although they are deflected by the magnet. His conclusion, that the kathode rays are not streams of electrified particles, was largely founded on this, and on another experiment on the action of electrostatic force on the particles. This experiment on the magnetic action of kathode rays is quite inconclusive, and it is very remarkable that Hertz should have attributed much importance to it. Whatever current was carried down his tube by the kathode ray must have come back the tube by the surrounding gas, and these two opposite currents should have produced no magnetic force outside the tube; and this is exactly what Hertz observed. In a similar way, what he observed in the case of a flat box was the average direction of the current, and he showed that this average direction was approximately the same as in a conducting sheet. This proved that if there were any concentration of the current along the direction of the kathode rays, this concentration was neutralised by a corresponding return current, so that the average current was as described. At the same time there does not seem much doubt but that the kathode rays only carry a very small part of the current. The third part of the paper is concerned with the electrostatic effects due to kathode rays. The experiments do not seem to fully justify the conclusion drawn, that kathode rays cannot be charged molecules. Sufficient account does not seem to have been taken of the shielding action of the conducting gas surrounding the kathode ray, nor of the way in which the potential is distributed between two electrodes in a gas. Hertz describes an experiment with two plates inside the tube kept at a considerable difference of potential. He says: "The phosphorescent image of the Ruhmkorff coil discharge appeared somewhat distorted through deflection in the neighbourhood of the negative strip; but the part of the shadow in the middle between the two strips was not visibly displaced." Now this is exactly what one might expect, because the fall of potential between two such strips is very small indeed, except close to the negative strip, and there the electric force *did* deflect the rays. Hence the conclusion is just the reverse of the one Hertz gives. From the experiment it appears that kathode rays do behave like electrified particles. It is very

remarkable that in all these investigations Hertz does not once even mention, as a thing to be explained, the repulsive actions which Crookes observed, and which have been almost universally attributed to the impact of gas particles.

The other important paper, on the transmission of kathode rays through thin metallic films, is particularly interesting as the starting-point for Lenard's work, which has resulted in the discovery of the X-rays. A good deal of what Hertz observed would be accounted for by the production of X-rays where the kathode rays meet the diaphragms, and by the reproduction of kathode rays mixed with X-rays on the other side of the diaphragm, which would thus act as a sort of local electrode. That something exists in a vacuum on the far side of such a thin film, which does not ordinarily exist in X-rays in air, seems conclusively proved by there being something there which can be deflected by a magnet. There seems no doubt that kathode rays themselves are quite invisible, and that it is only where they are interfered with by gaseous molecules or by phosphorescent solids that they are sources of light. This is very much what one would expect. An electrified atom would not in general be a source of light unless its free movement were interfered with by impact.

The concluding article, on his master Helmholtz's seventieth birthday, is a noble and generous tribute to that great teacher's abilities and character. How truly he portrays the important characteristics of a University Professor! "It is true that Helmholtz never had the reputation of being a brilliant university teacher, as far as this depends upon communicating elementary facts to the beginners who usually fill the lecture-rooms. But it is quite another matter when we come to consider his influence on trained students, and his pre-eminent fitness for guiding them in original research." The most important duty of a University is to increase the knowledge of mankind, and to train up a new generation who may be able to continue the good work. It is thus mankind has advanced since the dawn of civilisation in Egypt. He who produced the most enthusiastic disciples has most advanced the well-being and the well-living of the race. G. F. F. G.

THE BUREAU OF ETHNOLOGY AT WASHINGTON, U.S.A.[1]

THE Bureau of Ethnology at Washington has, during the last sixteen years, been carrying quietly on a work of the importance of which, we feel sure, that a number of students of anthropology have no knowledge whatever; we are equally sure that work itself, as well as those who labour in it, has not received due recognition. It is now nearly thirty years since the exploration of the Colorado River of the West was begun by the Act of Congress in America, and it is nearly twenty years since the various geographical and geological surveys which sprang up in connection therewith were dissolved, and since the foundation of the United States Geological Survey became an established fact. In the course of the work carried on by the Survey its various members made most exhaustive anthropologic researches among the North American Indians, and the myriads of facts which these self-sacrificing workers collected were fortunately rescued for the benefit of all students, and for all time, by the beneficent help of the Smithsonian Institution, which had secured provision for the publication of a series of monographs on almost every subject connected with the manners and customs, history, religion, and languages, &c., of the various Indian tribes with which they came in contact. Under the authority of the Act of Congress, the Secretary of the Smithsonian Institution entrusted the management of this great work to the former Director of the Rocky Mountain Region Survey, Mr. J. W. Powell, and thus the Bureau of Ethnology was practically established. It is a pleasant thing to be able to record that Congress supported the work both with patronage and with pecuniary assistance, and all will confess that the contributors to the success of the Bureau have worked with a will so as to employ in the best possible manner, and to the best possible end, the funds which have been placed at their disposal. We have before us thirteen handsome volumes of Reports, each containing several hundred pages of closely-printed matter, and profusely illustrated with well-executed coloured plates, and many hundreds of woodcuts. No reviewer of these volumes could attempt to give an adequate account of them unless he had some scores of pages at his disposal, and it goes without saying that all that any writer can do here is to call attention to the plan of Mr. J. W. Powell's volumes and to the general contents, hoping that the reader will devote some portion of his leisure to the perusal of a set of works which are at once of the greatest interest to those who study man and his ways, and of the first importance to the student of ethnography.

In setting out on his work, Mr. J. W. Powell says that throughout "prime attention has been given to language," for "with little exception all sound anthropologic investigation in the lower states of culture exhibited by tribes of men, as distinguished from nations, must have a firm foundation in language. Customs, laws, governments, institutions, mythologies, religions, and even arts cannot be properly understood without a fundamental knowledge of the languages which express the ideas and thoughts embodied therein." As a result of this opinion, the officials of the Bureau of Ethnology have devoted themselves to collecting materials for dictionaries of the North American languages, and for chrestomathies, and in time they hope to put grammars of the same before the world. With a view of enabling the philological student to determine what help he may or may not be able to obtain from these languages, the authors of the volumes before us give, every here and there, selected texts accompanied by interlinear transliterations, much in the same way as the early Egyptologists used to do in publishing hieroglyphic texts; and there is no doubt that this is a most useful plan. That it enables the careful reader, at times, to trip up his editor is true; but it is an honest method, and will be much appreciated by all painstaking students, for comparisons of words can thus easily be effected. Turning, though only for a moment, from language and from the characters which express language, that is to say writing, we see at a glance that the peoples of North America had many things in common with the most ancient civilised nations of antiquity. We do not for a moment believe that every custom and belief which may be found among them should be used to connect them with the ancient Chinese, or Indians, or Babylonians, or Egyptians; but it seems perfectly clear that every primitive nation, wherever it may live on the globe, or whatever may be the circumstances under which it lives, has certain fundamental ideas about the future life, and religion, and morality, which closely resemble those of other early nations. It seems tolerably clear, too, that many anthropologists have erred somewhat in tracing connections between peoples of totally different races, which they have deduced from observing that they had many beliefs in common. A careful examination of the characters employed by early nations to express their ideas makes this quite plain, for as pictures were used by them all for this purpose, we have only to trace the conventional sign back to its oldest form to find out what fundamental ideas existed in their minds. Primitive

[1] The Annual Reports of the Bureau of Ethnology to the Secretary of the Smithsonian Institution, by J. W. Powell, Director. 13 Annual Reports. (Washington: Government Printing Office, 1881-1896.)

man, wherever he existed, used as writing materials such natural objects as were readily obtainable. Strips of bark, dressed skins, pieces of wood, bones, flat pieces of slate or stone, rocks, clay, &c.; when he was sufficiently advanced to beat out or to cast plates of metal, iron and bronze were also used by him for this purpose. At a later period he found out the way to make papyrus and paper, and this once done the task of the writer was comparatively simple. His pen varied with the substance which he wrote upon; wood, stone and metal demanded a hard, sharp instrument, and skin and paper demanded only an object which would transmit the writing fluid to their surface in regular quantities at the will of the writer. Ink was in its earliest form simply a mixture of water with some burnt vegetable substance or mineral earth. The style and character of the writing were modified by the materials used; and this is only a natural result when we consider how easy it is to draw circles, curved lines, and intricate devices upon a smooth substance like dressed skin or paper, and how hard it becomes to cut the same in stone. From the Chinese and cuneiform characters we may learn how, little by little, the original picture forms disappeared before the general use of stone and clay, and we know that the style of writing which was used for State documents was very different from that employed in the ordinary business of life. In the clay tablets of the last Assyrian Empire, about B.C. 700, the cuneiform characters bear no resemblance whatever to those which are found on the monuments of the period of Entenna, about B.C. 4500; in the Demotic writing of Egypt, so far back as the period of the Ptolemies, the pictorial character of the ancient hieroglyphics (from which it was derived, through the intermediate form of the hieratic or cursive form of writing employed by the priests) has quite disappeared. When we come to consider the characters used for writing purposes among the North American Indians, so ably discussed by Mr. Garrick Mallery (see "Sign Language among North American Indians," in the *First Annual Report of the Bureau of Ethnology*, p. 263 ff.), we find many pictures which show that they have much in common with picture signs in other languages. The sun is represented by a circle, as in Egyptian and Babylonian; sometimes it has rays shooting out all round it, just as we may see it in one of the vignettes of the ninety-second chapter of the "Book of the Dead." Sunrise is symbolised by a part of the disk showing above the ground; in Egyptian the disk is seen rising between two mountains. The star is represented by a small circle with four rays shooting from it, each towards a cardinal point; in Egyptian the star often has five points, but one of them probably represents the rope or chain by which the Egyptians thought it was hung out in the sky, and in Babylonian a star usually has eight points. The moon is represented by a crescent, as in Egyptian, Chinese, and Babylonian; heaven is a vaulted space, but in Egyptian it is drawn like the flat roof of a house, and has, moreover, supports by which it stands firm on the earth. To represent clouds a number of dark conical masses are drawn within the vault of heaven; the common Egyptian determinative for words meaning cloud is a tress of hair, and it is probable that this idea is common to both Egyptians and Indians. Similarly among both peoples rain was represented by lines of water falling from the sky. In fact it would seem that natural objects, both animate and inanimate, were written always in the same way, whether the writers were Chinese, or Egyptian, or Babylonian, or people of Western Asia, or the makers of the Cretan pictographs which Mr. A. J. Evans has discovered, or North American Indians. Abstract ideas were probably expressed quite differently by all nations; but even to touch on this far-reaching subject would be beyond the scope of this short notice. It must, however, be mentioned in passing that Mr. Garrick Mallery has collected a series of most important facts in connection with this subject in his "Pictographs of the North-American Indians" (see *Fourth Annual Report of the Bureau of Ethnology*), a work which should be consulted by all who study the history of the development of writing in the world, and that he has further supplemented our knowledge of the subject by his later work, "Picture-writing of the American Indians" (see *Tenth Annual Report of the Bureau of Ethnology*). It is a curious fact that the peoples of North America did not invent an alphabet, as many of the other nations of the world have done, for it is clear to every one that a system of picture-writing, however simple, is really a cumbrous affair, and the misreading of a picture sign might be at times accompanied by dire consequences. At a very early period Chinese, Babylonians, and Egyptians introduced an alphabetic principle into their writing, and the Persians succeeded in abolishing entirely the picture element from their system. The other volumes of Reports are, each in its way, as interesting as those to which we have called attention, and from them we may learn that light and information can come from the West as well as from the East. The carefully made collections of ethnological facts, which we find in the series of works issued under the able direction of Mr. Powell, should do much to help and encourage other workers in their inquiries, and the scholarly way in which they have been set forth by his fellow-workers reflects the greatest credit upon the Smithsonian Institution, and upon all who have been connected with their publication.

NOTES.

IT is stated that Lord Rayleigh has intimated to the Council of the Royal Society that he does not intend to seek re-election as one of the Secretaries of the Society.

THE President of the Royal Society (Sir Joseph Lister) will preside at Prof. Dunstan's lecture at the Imperial Institute next Monday evening.

LORD KELVIN has been suffering for some time past from severe neuralgia in the head; but he is now much better, and was able on Saturday to attend at the Royal Society for an hour.

THE celebration of the seventieth birthday of Prof. Stanislao Cannizzaro at Rome has been postponed to November 21, on account of the anniversary on July 12 falling in the University vacation. A Committee has been formed and has collected subscriptions, which are to be devoted partly to the production of a gold medal commemorative of the anniversary, the balance being handed to Prof. Cannizzaro to be applied at his discretion in the interests of science. Congratulatory addresses will be presented from various learned societies, and there will also be a ceremonial presentation of the medal and subscribed fund.

THE recent Conference at Burlington House on the proposed International Catalogue of Scientific Publications appears to have stimulated interest in the subject-index to the Royal Society's "Catalogue of Scientific Papers," upon which the Society's staff is already engaged. The College Section of the American Library Association at their meeting last month unanimously passed the following resolution:—"That the Section has learned with great satisfaction that the Council of the Royal Society proposes to add to the debt which the scientific world already owes to it for its valuable 'Catalogue of Scientific Papers,' by making a subject-index to the papers contained therein."

A MEETING of the executive committee which has been formed in connection with the submarine telegraph memorial, was held on Friday last. Two resolutions were adopted as follows:—"That it is desirable to establish a memorial to the late Sir John Pender, G.C.M.G., to commemorate the leading part he took in the establishment and development of submarine telegraphy, and in its extension throughout the world." "That measures be taken for promoting in the year 1901 a general international memorial recording the jubilee of international submarine telegraphy." A meeting of the general committee will be held in about a fortnight, when the decision arrived at will be submitted for confirmation.

CHRISTMAS lectures specially adapted for children will this year be given at the Royal Institution by Prof. Silvanus P. Thompson, F.R.S., his subject being "Visible and Invisible Light." Prof. Augustus D. Waller, F.R.S., has been appointed Fullerian Professor of Physiology for three years, the appointment to date from January 13, 1897; and Dr. Alexander Scott has been made the Superintendent of the Davy Faraday Research Laboratory of the Royal Institution, the Directors being Lord Rayleigh and Prof. Dewar.

MR. R. ETHERIDGE, late of the Geological Department of the British Museum, has been awarded by the Royal Geological Society of Cornwall its first Bolitho gold medal, in consideration of his services to Palæontological science.

THE objects exhibited in the ethnographical section of the Millennial Exhibition at Budapest are to be used as the nucleus of an ethnographical museum. The collection of machines in the special exhibition of the means of transport are to form a railway museum, and the bulk of the exhibits in the agricultural section will be used for the foundation of an agricultural museum.

A REUTER correspondent at St. John's reports further mineral discoveries in Newfoundland. An immense deposit of silver and lead ore has been discovered at Lawn, on Placentia Bay. The lode is said to be one mile long and 18 feet deep, and is described as very rich. An offer of £50,000 for the mining rights is reported to have already been made. Rich gold-bearing quartz reefs have been found at Ming's Bight, 200 miles north of St. John's.

SCIENCE has just lost an eminent investigator and teacher by the death of Dr. H. Newell Martin, F.R.S., late professor of biology in the Johns Hopkins University, Baltimore, U.S.A. In conjunction with Huxley, Prof. Martin wrote a manual of "Practical Instruction in Elementary Biology," which was published in 1875. He was also the author of a number of textbooks of physiology; and the seventh edition of his admirable volume on the structures and activities of "The Human Body" reached us only a few days ago. Prof. Martin was in his forty-eighth year.

IT is reported in *Science*, upon the authority of the Honolulu correspondent of the United Associated Presses, that Mr. C. R. Bishop has authorised the Trustees of the Bishop Museum to expend 750,000 dols. in building an aquarium and marine biological station at Honolulu, for the scientific study of marine life in the Pacific. Prof. W. T. Brigham has just returned from visiting European aquariums, and is prepared to complete the plans. A body of professors and investigators will be maintained, and students will doubtless be attracted from Europe and America.

WE regret to announce the death of Dr. Moritz Schiff, professor of physiology in the University of Geneva, at the age of seventy-six; of Dr. Julius T. Wolff, the director of the private observatory—Photometrisches Observatorium—at Bonn, and the last of Argelander's pupils, at the age of seventy-six; of Prof. Dr. Eugen Sell, honorary professor of chemistry in Berlin University, at the age of fifty-four; and of Prof. Gustav Kiesewitski, professor of mathematics at the Polytechnic Institute in Riga.

THE death is announced of M. Lucien Trécul, an eminent botanist, and member of the Paris Academy of Sciences. The Paris correspondent of the *Chemist and Druggist* gives the following particulars as to Trécul's life:—"He was seventy-eight years of age, having been born at Mondoubleau (Loir and Cher) in 1818. He studied pharmacy in Paris, and became a hospital pharmacist in 1841, his best-known contemporaries being MM. Chatin, a former director of the Paris School of Pharmacy, and Georges Ville, professor of agriculture at the Museum. About this time Trécul was attracted by the study of botany, and soon afterwards devoted himself entirely to it. Early in 1848, he was asked by the Minister of Agriculture and the Paris Natural History Museum to go to the United States to study the feculent roots used for alimentary purposes by the Indian tribes of North America. He left France early in the same year, and for a long time followed an Indian tribe in its wanderings over the prairies near the Rocky Mountains. He got together a superb collection of plants and animals. The ship carrying them to France was, however, lost in a storm during her voyage. M. Trécul, not discouraged, recommenced his work. He proceeded to Texas and Mexico, from whence he sent valuable collections to the Paris Museum." He was a Chevalier of the Legion of Honour, and became a member of the Paris Academy of Sciences in 1856. For the past forty years, or more, he lived a very secluded life, and was only heard of by occasional communications to the Paris Academy, and through his written works.

NANSEN'S narrative, the forthcoming publication of which, in a newspaper, was warmly referred to in a note last week, appeared in the *Daily Chronicle* of Monday, Tuesday, and Wednesday. Never before, in our knowledge, has such a stirring story been told of life amidst the ice and snow of the frozen north, and certainly never has the pages of a daily paper been embellished with such brilliant illustrations as those which accompany Nansen's articles. Naturally the account deals almost entirely with the adventurous aspect of the expedition; and as this was summarised (from telegrams communicated by Nansen to the *Daily Chronicle*) in our issues of August 20 and September 3, no useful purpose would be served by repeating the descriptions then given. The geographical results of the expedition, so far as they have yet been made known, were brought together by Dr. Mill in an article which appeared in these columns on August 27. In his three articles in the *Chronicle*, Dr. Nansen carefully avoids going into any scientific details, and he is probably reserving these for the paper he will read before the Royal Geographical Society early next year. One or two natural history observations are, however, mentioned in the course of the narrative. In the neighbourhood of four islands in latitude 81° 38′ N. and longitude 63° E., in August 1895, large numbers of the rare Ross's gull (*Rhodostethia rosea*) were seen. We read: "This, the most markedly polar of all bird forms, is easily recognisable from other species of gull by its beautiful rose-coloured breast, its wedge-shaped tail, and airy flight. It is without comparison the most beautiful of all the animal forms of the frozen regions. Hitherto it has only been seen by chance on the utmost confines of the unknown Polar Sea, and no one knew whence it came or whither it went; but here we had unexpectedly come upon its native haunt, and although it was too late in the year to find its nests, there could be no doubt about its breeding in this region." From November 1895 to March 1896, no bears were seen, but foxes, both of the white variety and of the valuable dark-furred kind, constantly

came to the hut where Nansen and Johansen passed the winter. With the spring, a few days after the sun had appeared above the horizon, a flock of little auks was seen sailing past along the mountains to the north, and soon the mountains swarmed with them. The whole of that part of Franz Josef Land traversed by the two explorers consisted of basalt, and once formed a continuous basaltic land, which is now, however, cut up into small islands. On the south side of the country a deep stratum of Jurassic clay occurs beneath the basalt, and in it was found numerous ammonites and belemnites. The proprietors of the *Daily Chronicle* deserve every credit for their enterprise in arranging to pay Dr. Nansen so much as 1500*l.* for the telegraphic account of his expedition, and 4000*l.* for the articles just published.

WE are pleased to be able to report that Prof. W. J. Sollas returned to Dublin, in the best of health, on October 28, from his travels in the Pacific. It will be remembered that the Royal Society gave a grant to a Committee to investigate a coral reef by boring, sounding and other methods, and the island of Funafuti, in the Ellice Group, West Pacific, was selected as being a promising atoll. We have already (NATURE, vol. liv. p. 517) noted that the boring was unsatisfactory; but the other portion of the programme was successfully carried out, and large collections of the land and marine fauna were severally made by Prof. Sollas, Mr. C. Hedley, of the Australian Museum, Sydney, and Mr. Stanley Gardiner. The party also collected plants and all the objects of ethnographical interest on the island. Dr. Collingwood made measurements of the natives, and other observations on their physical anthropology. Prof. Sollas carefully studied the physiography and geology of the island, and kept daily records of the maximum and minimum temperatures. The soundings made by the *Penguin*, under Captain Field, were so complete that an accurate contour map can be made of the submarine slope; probably in no case has a coral island been so accurately surveyed. Numerous photographs were taken by Prof. Sollas and Dr. Collingwood. The expedition was eleven weeks on the island. Prof. Sollas then proceeded to Fiji, where he stayed about a month and made a special geological tour in the interior, accompanied by the Hon. Dr. Corney and the Hon. Mr. Udal. We understand that results of some importance will follow from this journey. After calling at Samoa, Prof. Sollas went to Honolulu and made some geological observations in the islands of Oahu and Hawaii. Mr. Hedley returned with his collections to Sydney, where he is working out his results. Mr. Gardiner is now in Rotumah. We hope that it will be possible to include *all* the results of this expedition in a single publication, instead of their being published in scattered papers. If this were done, we should have such an account of the physical structure, flora, fauna, and anthropology of a single coral island as has never yet been brought together in one volume. The scientific men associated on the expedition are now so widely scattered, that no time should be lost if their various observations are to be collected and coordinated.

THE committee appointed by the Entomological Society, for the protection of British Lepidoptera in danger of extermination, held a meeting on October 14; Prof. Meldola, President of the Society, being in the chair. Letters from the City of London Entomological and Natural History Society, the North London Natural History Society, and the Leicester Literary and Philosophical Society, expressing warm sympathy with the object of the committee, were read. After discussion of the best methods of securing the object of the committee, it was resolved to invite information as to species in special danger of extermination, with a view to future action.

HE is a bad workman who grumbles at his tools, and the student of science who neglects research because he does not possess apparatus ready-made and varnished by the instrument-maker, lacks the spirit of the investigator. Test the efficiency of the things at your disposal is good advice, for the knowledge and experience gained by direct communion with nature, even through the roughest apparatus, is a very valuable educational training. Because this is so, and because we hold our highest function to be the encouragement of research, we have pleasure in noting that "a Yorkshire lad," Mr. G. W. Watson, of Keighley, has obtained some wonderfully good Röntgen photographs by using an old home-made Wimshurst machine to illuminate a Crookes' tube. The machine gave a spark about 1¾ inches in length, and was without condensers. With this primitive equipment, good radiographs of the bones of the hand were obtained in twenty minutes. One of these pictures, and also a radiograph of an abnormally developed elbow, have been submitted to us; and both are very creditable productions. The definition is unusually clear, and the hollow structure of the bones is distinctly visible. Mr. Watson's success may induce others to see what they can do with simple means.

WHILE the bison of North America is on the point of extinction, the European bison, which is still found in Russia and the Caucasus, is sensibly decreasing in numbers, in spite of the efforts made for its protection by the Imperial Government. Herr Buchener (says the *Zoologist*), in a memoir on the subject recently presented to the Imperial Academy of Sciences at St. Petersburg, regards it as likely soon to share the fate of its American relative. In the forest of Bialowicksa, in the province of Lithuania, a herd of these fine animals has long been preserved, and forty years ago, namely in 1856, numbered about 1900, but of late years this has dwindled down to less than 500, and there is no encouraging sign of any material increase. Our contemporary points out that if the Russian Government would only give instructions to have some of the Caucasian bison captured alive and transported to Lithuania for the purpose of resuscitating the herd there, no doubt in a few years a marked improvement might be effected. The enterprise would necessarily be attended with considerable difficulty and great expense, but in view of the scientific importance which would attach to the result of the experiment, it would be well worth undertaking.

THE renowned "Bourbon" sugar-cane is so subject to diseases, particularly to attacks of Rind fungus, that the question of the most profitable variety of cane for cultivation in the Leeward Islands is of much interest and importance to the colony. Some facts are brought to bear upon this question in a report by Mr. F. Watts and Mr. F. R. Shepherd, published as a supplement to the *Leeward Islands Gazette*, detailing the results of experiments on the cultivation of different varieties of sugar-cane with the view of ascertaining which varieties are best able to resist disease. The results of their observations show that the best canes for planting in Antigua are those designated White Transparent, Naga B, Red Ribbon, Caledonian Queen, and Queensland Creole. These varieties held their own under different conditions of drought and infection; they were free from Rind fungus, and yielded juices of high purity and great saccharine richness. The Keni Keni cane, which, when it was first introduced into the colony, gave the best yield of any, has now fallen practically to the bottom of the list. It is an ally of the Bourbon, and is badly attacked by the Rind fungus. A curious fact is that both the Bourbon and Keni Keni canes should deteriorate in this manner, though the latter seems to have changed for the worse much more rapidly than the former. Further observation on this point would be of considerable interest in connection with the stability of varieties in relation to disease.

NOT so very long ago, the proposal to raise sugar-canes from the seeds would have been treated with ridicule, but, thanks to the work at Demerara and Barbados, and the experiments at the

Royal Botanic Gardens, Trinidad, it is now known that the sugar-cane will grow from seed, and that remarkable variations are produced. A short account of the share taken by the Trinidad Gardens in raising these seedlings is given in the Trinidad *Bulletin of Miscellaneous Information*, by Mr. J. H. Hart, the Superintendent. As a result of the experiments, sugar-canes have been produced that have given 25 per cent. above the yield of varieties commonly grown. If these varieties can be successfully got into plantations on a large scale, no further proof will be required of the value of the work done by Botanic Gardens. It is proposed to distribute cane plants of the new varieties early next year, and we trust that the results of their cultivation will be satisfactory in every sense of the word. Mr. Hart points out that the effort of the raisers of the sugar beet have long been directed to secure a strain of plants that would, while giving a large yield per acre, afford at the same time the maximum amount of sugar, and their efforts have been attended with great success, for it is well known that the yield from roots cultivated of recent years show a tremendous advance over the percentage yielded by the beet twenty years ago. Had the yield of the cane increased in the same proportion as that of beet, the sugar industry would not have suffered as it has done of late.

PROF. RALPH S. TARR contributes to *Science* a description of the recent expedition to Greenland, conducted by Lieut. Peary. The principal geological results are briefly stated as follows:—"At Turnavik, on the Labrador coast, evidence of recent glaciation is abundant. The hills are all rounded; there has been little post-glacial decay, and the transported boulders, as well as the bed rock, are very fresh. Upon exposed rock faces, unprotected from the weather, glacial striæ are still very distinct. Granting equality of weathering, this region has been much more recently glaciated than regions of similar geological structure in New England. The amount of glacial carving has not been sufficient to lower the surface of the gneiss to the level of the pre-glacial decay in the trap-dike valleys." On Big Island and the neighbouring coast of Baffin Land, evidence of very recent elevation was found up to a height of 270 feet above sea-level. The results of the study of the Nugsuak peninsula are interesting. The peninsula extends twenty-four miles from the front of the Cornell glacier to the end at Wilcox Head, while the Duck Islands are at a distance of eight or ten miles from the mainland. The Cornell glacier was found to have undergone recently a rapid withdrawal, and its retreat is believed by Prof. Tarr to be a part of a general withdrawal of a vast ice sheet, which extended outward beyond the Duck Islands. The entire Nugsuak peninsula has been so recently glaciated, that striated rocks are still present even at the outer end.

ACCORDING to the usually accepted theory of Crookes' tube, antikathodic rays are produced wherever kathodic rays impinge on a fixed obstacle. In the *Bulletin de l'Académie Royale de Belgique*, M. P. De Heen advances the theory that these rays result from encounters between molecules projected from the anode and kathode respectively. In verification of this view, experiments were made with a tube in which the usual anode was replaced by two parallel laminæ of aluminium at a small distance apart. When either of these laminæ was used as anode, the kathode being at the other end of the pear-shaped tube, antikathodic rays were observed; but these disappeared entirely when the two parallel laminæ were used as anode and kathode respectively. This result was easily explained by the fact that the space between the two surfaces was too small to allow of frequent collisions taking place between the anodic and kathodic projections. On the ordinary theory, however, the kathodic projections would traverse the space between the laminæ with great facility, thereby giving rise to a copious emission of antikathodic rays, contrary to observation.

THE *Proceedings* of the fifty-fourth meeting of the American Association for the Advancement of Science, held at Springfield, Mass., in August and September 1895, have lately been published.

IN the *Meteorologische Zeitschrift* for October, General Rykatcheff publishes a note on the meteorological observations at the St. Petersburg and Pavlovsk observatories during the solar eclipse of August 9.

THE *Bulletin of the Torrey Botanical Club* for September reprints Dr. N. L. Britton's brief account of the Botanical Gardens of the world, given as the vice-presidential address before Section G of the last meeting of the American Association for the Advancement of Science. The total number is given as over 200, but some of them are little more than pleasure parks. Of the total number, Germany possesses 36, Italy 23, France 22, Russia 16, Austro-Hungary 13, Great Britain and Ireland 12, and the United States 10.

THE *Bibliothèque universelle*, a monthly review now published in Lausanne, Switzerland, has recently celebrated the hundredth anniversary of its foundation. It was originally established in Geneva, under the title *Bibliothèque britannique*, by Frédéric Guillaume Maurice and the brothers Marc Auguste Pictet (pupil and friend of the famous naturalist Saussure) and Charles Pictet de Rochemont, its chief object being the diffusion of English ideas and scientific researches in France and Switzerland. It numbered among its earliest contributors Sir Humphry Davy, Edward Jenner, Sir Joseph Banks, the physicist Charles Earl of Stanhope, and, at a somewhat later period, Sir John Herschel.

ARRANGEMENTS are being made to commemorate the sixtieth year of the reign of Her Majesty Queen Victoria by an exhibition at the Crystal Palace, to be opened on May 24, 1897. It is proposed to illustrate by models and practical examples the famous inventions in arts and industries during the past sixty years, and also the progress of other sides of national development. As a sort of prologue to this exhibition, a series of popular lectures, dealing with the advancements in science made during Her Majesty's reign, will be delivered during March and April next.

THE next session of the Anthropological Institute commences on Tuesday, November 10. A number of interesting communications are promised, among others being papers by Prof. E. B. Tylor, on North American Wampum Belts; by Dr. Oscar Montelius, on the Tyrrhenians and the pre-classical period in Italy; by Dr. J. H. Gladstone, on the transition from the use of copper to the use of bronze; by Lieut. Boyle T. Somerville, R.N., on the natives of South Georgia (Solomon Islands); by Miss G. M. Godden, on the Nagas and other hill tribes of the North-East Indian frontier; by Dr. Colley March, Miss Christian Maclagan, and Mr. R. H. Mathews. At the first meeting Mr. H. Balfour, of the Pitt-Rivers Museum, Oxford, will exhibit a remarkable bow found in Egypt, and believed to be Assyrian, and will read the life-history of an Aghori Fakir, exhibiting drinking-bowls made from human skulls. Mr. C. H. Read will exhibit a curious wooden carving executed by a Haida Indian, apparently from a model of a sphinx; and a wooden dance-mask from the north-west coast of America. Mr. P. L. Sclater will exhibit a "draught-board" from Nyassaland; and Mr. Balfour will show a number of transparent sections of composite-bows of various times and countries.

TWELVE years have elapsed since the publication of Phillips's well-known and widely-consulted "Treatise on Ore Deposits." In this period the subject of metalliferous deposits has undergone such extensive changes, both material and theoretical, that Prof. Henry Louis, in preparing the second edition, which Messrs.

Macmillan and Co. will issue in a few days, has had to introduce many modifications of the original text, and make many additions. Especially is this the case in the first part of the work dealing with the classification and genesis of ore deposits. This has been entirely rewritten in order to bring it into accordance with modern ideas. The second part of the work, being mainly a record of facts and observations on ore deposits of the principal mining regions, has not needed to be recast, though the results of recent studies, and of newly-developed fields and deposits have been added. The work has thus been rejuvenated, and will continue to hold its high place among mining literature. Another new edition to be published by Messrs. Macmillan in a few days, is Ziegler's "Special Pathological Anatomy." The first English edition of this standard work was published in 1884, but the edition (the third) shortly to be issued differs from it very considerably, having been translated from the eighth German edition. So great have been the advances in pathological anatomy during the past twelve years, that the text has had to be completely rewritten. The forthcoming volume has been translated and edited by Dr. Donald MacAlister and Dr. Henry W. Cattell. The second volume of the work is in the press, and it will be followed by a new version of the part on general pathological anatomy.

THE researches of Émil Fischer on the action of phenylhydrazine on the various sugars have shown that either a simple hydrazone is formed, by the reaction of the aldehyde or ketone group of the sugar with the amido-group of the hydrazine, or that, in addition to this, the hydrogen atoms, combined with the carbon atom adjacent to the carbonyl group, are removed, and a second molecule of phenylhydrazine enters into reaction, an osazone being formed. In a paper published in the current number of the *Berichte*, E. Davidis describes two new types of hydrazine derivatives of the sugars, which have been obtained in the laboratory of Prof. Curtius. When a sugar such as glucose is warmed with hydrazine hydrate and a little methyl alcohol, two molecules of the sugar react with one of the hydrazine, and glucosaldazine, $C_6H_{12}O_5 : N.N : C_6H_{12}O_5$, is produced. Similar compounds are formed by fructose and arabinose, and they are all readily hydrolysed by dilute acids. Compounds of the second type are formed when the sugar is treated with an acid hydrazide, such as benzhydrazide, $C_6H_5.CO.NH.NH_2$, in the presence of dilute alkalis. Under these circumstances, no less than *four* molecules of the hydrazide react with one molecule of the sugar. The compound produced from glucose, which the author terms glucosebenzosazone, therefore resembles glucosazone in constitution, but differs from it inasmuch as the removal of the hydrogen atoms and reaction with the hydrazide has been extended to three consecutive carbon atoms. A portion of the benzhydrazide is simultaneously decomposed with formation of ammonia and benzoic acid. Lævulose yields precisely the same compound as glucose. It has, so far, been found impossible to prepare a benzosazone containing either more or less than four hydrazine groups. These compounds crystallise well, and melt at a comparatively high temperature; and it is therefore possible that they may play an important part in the investigation of the very complicated group of compounds to which the sugars belong.

THE additions to the Zoological Society's Gardens during the past week include a Mozambique Monkey (*Cercopithecus pygerythrus*, ♂) from South-east Africa, presented by Dr. John Archibald; a Hocheur Monkey (*Cercopithecus nictitans*, ♂) from Congoland, presented by the Rev. Lawson Forfeitt; a Syrian Bear (*Ursus syriacus*, ♀) from Western Asia, presented by Mr. G. A. Schenley; a Garden Dormouse (*Myoxus quercinus*), European, presented by Mr. W. H. St. Quintin; two White Storks (*Ciconia alba*), European, presented by Miss Agnes Woodroffe; a Black-backed Piping Crow (*Gymnorhina tibican*) from Australia, presented by Mr. Charles G. Murrell; four European Tree Frogs (*Hyla arborea*) from Italy, presented by Mrs. Kneeshaw; a Beccari's Cassowary (*Casuarius beccarii*) from New Guinea, a Night Heron (*Nycticorax griseus*), two Purple Herons (*Ardea purpurea*), European, two Black-spotted Teguexins (*Tubinambis nigro-punctatus*) from South America, deposited; two Common Sheldrakes (*Tadorna vulpanser*), European, three Mandarin Ducks (*Æx galericulata*) from China, a White-faced Tree Duck (*Dendrocygna viduata*) from Brazil, received in exchange.

OUR ASTRONOMICAL COLUMN.

STRASSBURG OBSERVATORY.—The first contribution to astronomical science of the Kaiserlichen Universitäts-Sternwarte in Strassburg is contained in a handsome volume just published by the Director of the Observatory, Prof. E. Becker. This observatory, it may be remembered, was instituted in the year 1872, Dr. August Winnecke being called upon to fill the post of Professor of Astronomy, and make plans for the arrangements of the buildings and instruments. It is quite worth while recording the fact that almost one of the first acts of Germany after the conclusion of the war, was to arrange for the building of this observatory, showing that, to have an astronomical observatory, which should be a seat "der exacten Wissenschaften," was almost as important as a fortress. No less extraordinary is it that this volume of the "Annalen," just published, should contain the first full description of the buildings and instruments almost fifteen years after they have been set up. We are led to infer from this that the object of the Germans is, in any case, to collect facts, even if they cannot momentarily be published. The buildings were commenced in 1877, and by the summer of the year 1881 work had already begun. In this, the first volume of the "Annalen," Prof. Becker gives a full description of the different buildings and of the various instruments housed in them, illustrating them with eighty excellent photogravure plates. Among these latter are a large refractor of 487 mm. aperture and 7 m. focal length, by Merz, on a mounting by the brothers Repsold; a large comet-seeker with an objective, by Merz, of 162 mm. aperture and a focal length of 1·3 metres; a smaller comet-seeker, a transit instrument by Cauchoix, an orbit-finder (Bahnsucher), an alt-azimuth, and a Repsold meridian circle, having an object-glass of 160 mm. diameter and a focal length of 1·888 metres, by Merz. A thorough and complete investigation of this last-mentioned instrument was undertaken, the results of which are given in full detail. The observations which are here published extend from 1882 March 15 to 1886 September 9, and consist of meridian observations of the sun and chief planets, and of those stars, the positions of which were required for such different objects as comparison stars of comets, angular values of the heliometer scales, longitude determinations. In June 1884 the programme of work was considerably increased, the determination of the positions of 306 Anschlussstерne for the southern zones, and also of eighty-three stars of the southern fundamental catalogue of the Astronomischen Gesellschaft being the chief additions. Following the list of observations are the corrected readings of the meteorological instruments, the temperatures in the basement under the transit circle, and a short account of the climate of Strassburg as gathered from the meteorological observations made from 1873–79.

MARS IN AUGUST LAST.—Prof. V. Cerruli contributes some of his notes on the appearance of the Martian disc, during last August, to *Astr. Nach.*, No. 3384. Of the southern cap, he says, we have no sign. This fact cannot be accounted for solely by reason of perspective; it seems, however, that the southern snows, which diminished very rapidly in June and July, have undergone complete liquefaction. (The southern solstice occurred on July 13.) Ramification of the northern snow took place, according to his opinion, on August 25; on that day he observed for the first time "a flash of lightning more or less intense at the extreme north of Elisium," and this apparition was successfully repeated on the following days. It may be mentioned here that the bright flashes noted by the Lick observers, and others, were seen towards the southern pole in the region known as Chersonesus. With regard to the canals, he says that he was

able to identify a great many. Nilosyrtis appeared, however, very dim and small when compared to the Syrtis Major, which, at this time, is "probably in its maximum state of expansion." Ceberus, on the other hand, was observed to be very straight, wide and dark, and, it was thought, exhibited signs of gemination.

"HIMMEL UND ERDE."—The first number of the ninth year of this monthly contains many articles and notes of astronomical interest. Dr. G. Witt, of Berlin, contributes an account of the present state of our knowledge with regard to the planet Saturn, this being the first of two articles on this subject. The question of the origin of the surface markings on our satellite, the moon, is next raised, and the explanation given by Lœwy and Puiseux is brought into discussion. There are, also, two short notes on the rotation period of Venus and a remnant of the Biela comet. The former deals with Perrotin's work, while the latter informs us that Mr. W. E. Hidden, of Newark, U.S.A., is in possession of a piece of the meteorite, weighing 4·090 kilograms, which fell on November 27, 1885, in the neighbourhood of the town of Mazapil. This has been handed over to him by the director (Prof. Bonilla) of the observatory in Zacatecas (Mexico) for a mineralogical investigation. A brief account is given, also, of the new meteorological observatory adjoining the hotel on the top of the Brocken, and a short summary of the new contributions on the measurements of the heights of clouds, by Prof. Kaiser, in Danzig, and Prof. Koppe, in Brunswick.

THE REPORT OF THE ROYAL COMMISSION ON VACCINATION.

THE Report of the Royal Commission on Vaccination is one of the most moderate, and certainly one of the most convincing that has come from any Royal Commission during recent years. The Commissioners have, for seven years, been occupied in making most careful inquiries at all sources as to the efficacy of vaccination in rendering children (and adults) less susceptible to infection by small-pox virus. No trouble has been too great, and no expense has been spared to obtain accurate information as to the truth of statements made by the witnesses who appeared before the Commission; as to the trustworthiness of figures placed in evidence; as to the nature of the disease alleged to be due to vaccination; and as to the exact share that legal compulsion has had in promoting or preventing the vaccination of children. The conclusions at which the Commissioners have arrived are evidently based on the most thorough conviction that the evidence before them, after the careful sifting through which it has gone, is to be thoroughly trusted, whilst their recommendations as regards the alteration in the methods of operation, registration, and legal compulsion certainly appear to be those best calculated to increase the efficiency of vaccination, concerning the value of which they are so thoroughly convinced.

The main considerations of the Commission are arranged under a series of headings, which may first be taken seriatim.

(A) "As to the effect of vaccination in reducing the prevalence of, and mortality from, small-pox." Here they conclude "(1) that it diminishes the liability to be attacked by the disease; (2) that it modifies the character of the disease, and renders it (*a*) less fatal, and (*b*) of a milder or less severe type; (3) that the protection it affords against attacks of the disease is greatest during the years immediately succeeding the operation of vaccination. It is impossible to fix with precision the length of this period of highest protection. Though not in all cases the same, if a period is to be fixed, it might, we think, fairly be said to cover in general a period of nine or ten years; (4) that after the lapse of the period of highest protective potency, the efficacy of vaccination to protect against attack rapidly diminishes, but that it is still considerable in the next quinquennium, and probably never altogether ceases; (5) that its power to modify the character of the disease is also greatest in the period in which its power to protect from attack is greatest, but that its power thus to modify the disease does not diminish as rapidly as its protective influence against attacks, and its efficacy during the later periods of life to modify the disease is still very considerable; (6) that re-vaccination restores the protection which lapse of time has diminished, but the evidence shows that this protection again diminishes, and that, to ensure the highest degree of protection which vaccination can give, the operation should be at intervals repeated; (7) that the beneficial effects of vaccination are most experienced by those in whose case it has been most thorough. We think it may fairly be concluded that where the vaccine matter is inserted in three or four places it is more effectual than when introduced into one or two places only, and that if the vaccination marks are of an area of half a square inch, they indicate a better state of protection than if their area be at all considerably below this."

It is evident from the statistics given that the protection afforded by vaccination against small-pox, though lasting for some time, is gradually lost, so that there comes a period when the protection is very slight indeed. Re-vaccination is naturally the first remedy that suggests itself to meet this difficulty, and from the evidence collected by the Commission from the various epidemics that have occurred, and from the vaccination statistics of the various public services, it is made very apparent that the value of re-vaccination as a preventive of small-pox can scarcely be over-estimated. The proof of this is so conclusive, especially where it is based on the observations made on the ordinary staffs of hospitals, nurses, and the like, who are brought into close contact with small-pox patients, that the re-vaccination statistics alone are sufficient to prove the value of vaccination. The position taken up by Sir Guyer Hunter and Mr. Jonathan Hutchinson in this question in their minority report, appears to us to be the only logical one that could be arrived at, although the limits that should be placed upon compulsion, spoken of elsewhere, would also limit us in regard to re-vaccination. Only these two Commissioners recommend that re-vaccination at the age of twelve should be compulsory, and on the same lines as the initial vaccination; but now that School Boards have their age registration of the children in attendance on their schools, it would surely not be a difficult matter to ensure the vaccination of children of that age, in order that they might be protected through a period during which the susceptibility to the disease, though less than in the earlier years of life, is still considerable; the period, too, during which interference with training for work and with production of work is a very serious matter for the individual, and a matter equally serious for the State.

(B) "As to the objections made to vaccination on the grounds of injurious effects alleged to result therefrom; and the nature and extent of any injurious effects which do, in fact, so result." In regard to this they say "a careful examination of the facts which have been brought under our notice have enabled us to arrive at the conclusion that, although some of the dangers said to attend vaccination are undoubtedly real and not inconsiderable in gross amount, yet when considered in relation to the extent of vaccination work done, they are insignificant. There is reason further to believe that they are diminishing under the better precautions of the present day, and with the addition of the further precautions, which experience suggests, will do so still more in the future." The remedy for this, apparently, is the employment of calf lymph, which would wholly exclude the risks as regards both syphilis and leprosy. The second danger does not concern the British public, whilst the risk of syphilis, although real, is an exceedingly small one, even when humanised lymph is employed, and could probably be wholly avoided by care in the selection of the vaccinifer. As regards erysipelas, eczematous eruptions, and vaccinia maligna, calf lymph vaccination appears to have few advantages over arm to arm vaccination. This question is dealt with more fully in the following section.

(C) "As to whether any, and, if so, what means should be adopted for preventing or lessening the ill effects, if any, resulting from vaccination; and whether, and, if so, by what means, vaccination with animal vaccine should be further facilitated as a part of public vaccination." Here again the use of calf lymph is recommended, especially for those who have any doubt as to the source of "arm to arm" lymph. Extension of the age period from three to six months, and the adoption of the legal methods now in vogue in Scotland, are strongly recommended. Special attention is called to the necessity for care and cleanliness, not only during the operation, but also in respect to the instruments used; to the desirability that the operation of vaccination should be done at the child's home, except under special circumstances, to the necessity for postponement of vaccination when erysipelas, scarlet fever, measles, or chicken-pox are prevalent in the neighbourhood of the child's residence, or at the place of vaccination, or on account of the general health of the child, bad surroundings, or other conditions rendering the

operation at the time undesirable. The following recommendations are also made. The vaccination vesicles should not be opened unless for some adequate reason. The preservation of lymph in tubes instead of dry points (the storage of calf lymph in glycerine?), the careful sterilisation of all instruments used (which should be as simple as possible), and the exercise of care that the insertions of vaccine matter be not placed too close together, so that the vitality of the tissues between them may not be injured. It is thus suggested that greater latitude should be given to the medical man in deciding as to when vaccination should take place. On the other hand, along with compulsion of the parent, compulsion on the medical attendant to attend (should any unfavourable symptoms occur prior to the time fixed for inspection) should be made, and that notice should be given to parents that they are empowered to summon the public vaccinator. It is also pointed out that in any case where a child requires medical attendance owing to illness supervening on vaccination, that it should be the duty of the vaccinator to render such attendance if required by the parent, and that he should receive a fee in respect thereof. The Commissioners go on to state that "in our opinion, if the precautions we have suggested were adopted, untoward incidents of vaccination, already rare, would become much rarer."

Concerning the conditions of vaccination that obtain in Scotland (p. 135 of the Report), it is probable that any legal action that may be taken as a result of the report of the Commission will be based, to a large extent, at any rate, on the provisions of the Scottish Vaccination Act. As pointed out in the *British Medical Journal*, the essential features in which this system differs from that in vogue in England are the following. Almost the entire work of vaccination is carried on by the family doctor, who is paid for the operation and for the succeeding visit, just as he would be paid for an ordinary visit to the child; so that the parents, and not the rates, are charged with the expense. This, however, is a matter of detail, and the Commission recommends that any medical attendance required in consequence of vaccination, is not to be charged against the parents, but against the State. In a few large cities, especially in those where medical schools are located, public vaccination is resorted to. In these cities the public vaccine stations are in most cases in connection with the medical schools, though in some instances they are subsidised by municipal funds. State registration of vaccination is associated with birth registration. When the birth of a child is registered, the registrar hands to the person registering a notice requiring that the child shall be vaccinated within six months of its birth; the notice is accompanied by the usual certificate forms for successful vaccination, postponement, and insusceptibility. Every half-year the registrar sends a note of all who have not complied with the vaccination regulations to the inspector of poor under the Parish Council (Board of Guardians). This list of defaulters is placed in the hands of the public vaccinator, who visits those children who have not been vaccinated at their own home, or sees them at the office or dispensary of the Parish Council. Should the parents refuse to accept vaccination at the hands of the public vaccinator, but not till then, legal pressure may be brought to bear upon the parents, as in England. Of course it is contended that vaccination under these conditions cannot be inspected by a public inspector, and that very great latitude is allowed to the medical man as to what may constitute efficient vaccination; but, on the other hand, the vaccination being done by a trusted medical adviser does not arouse the same opposition that it does in England, with the result that in Scotland vaccination is accepted almost as part of the condition of registration of the birth of the child. A most important consideration in the Scotch system is that, as the period is six months instead of three, many of the dangerous illnesses of very early life, during which such a large proportion of children die, are not put down to vaccination, as they so frequently are in England. It has been suggested, indeed, that this period of six months might, with advantage, be extended to twelve, except when small-pox is epidemic, when vaccination should be done as early as possible. It is a striking fact that during eleven years (between 1884 and 1894) the number of unvaccinated children, *i.e.* those unaccounted for to the registrar, never rose to more than 2¾ per cent., and in 1894 this was as low as about 2½ per cent. In the second half-year of 1892 only twenty-two prosecutions were instituted. There can certainly be little doubt that, although there may be slight disadvantages connected with the performance of vaccination by medical men at the homes of the children, these are of such a nature that they could very soon be got over, whilst the enormous advantages far more than outweigh any possible disadvantages. It has been pointed out there would be no need to take the child away from its home; consequently it would not be necessary to expose it to inclement weather, or to rough treatment of any kind, with the result that chills and broken vesicles would be of less frequent occurrence than under the present system. The possible danger of contracting erysipelas, scarlet fever, measles, and like diseases from other children at this time, would also be done away with, could attendance at public vaccination stations be dispensed with.

(D) "As to what means, other than vaccination, can be used for diminishing the prevalence of small-pox; and how far such means could be relied on in place of vaccination." In connection with isolation the Commissioners confess that they can see nothing to warrant the conclusion that in this country vaccination might safely be abandoned, and be replaced by a system of isolation; but whilst fully admitting the protective effect of vaccination, the Commissioners maintain that it does not diminish the importance of measures of isolation, or dispense with their necessity. They hold, moreover, that steps should be taken to procure a more general division of the isolation of small-pox patients than exists at the present time; and they recommend "(1) that common shelters which are not now subject to the law relating to common lodging-houses should be made subject to such law; (2) that there should be power to the local authority to require medical examination of all persons entering common lodging-houses and casual wards to see if they are suffering from small-pox, and to offer a reward for prompt information of the presence of the disease; (3) that the local authorities should have power to order the keeper of a common lodging-house in which there has been small-pox to refuse admission for such time as may be required by the authority; (4) that the local authority should be empowered to require the temporary closing of any common lodging-house in which small-pox has occurred; (5) that the local authority should have power to offer free lodgings to any inmate of a common lodging-house or casual ward who may reasonably be suspected of being liable to convey small-pox; (6) that the sanitary authority should give notice to all adjoining sanitary authorities of the occurrence of small-pox in common lodging-houses or casual wards; (7) that where the disease occurs the public vaccinator or the medical officer of health should attend and vaccinate the inmates of such lodging-houses or wards, except such as should be unwilling to submit themselves to the operation."

One remarkable fact in connection with this part of the question is that even the minority reporters against vaccination (only two in number, although at least four members of the Commission were supposed, originally, to be adverse to its use) can offer no new light on the question; any argument brought forward, in a half-hearted fashion, against the efficacy of vaccination, is based not so much upon actual statistics as upon a purely hypothetical basis.

The alternatives, improved sanitation and isolation, that are advanced in the minority report as being sufficient to take the place of vaccination, were of no avail during the Gloucester epidemic, during which vaccinators and non-vaccinators alike competed with one another in their zeal to have vaccinations and re-vaccinations performed at as early a date as possible; only as the population became well vaccinated did other measures appear to have any material effect in limiting the spread of small-pox. Of the extent of the vaccination that went on in this city, an idea may be gathered from the fact that during one period of seven days four public vaccinators operated on 548 patients for the first time, and re-vaccinated 1683. No medical man would for a moment desire to minimise the importance of improved sanitary surroundings and immediate isolation of small-pox patients in dealing with any outbreak of small-pox, and with the prevention of small-pox epidemics, but from the nature of the disease and the period during which the infective nature of the disease makes itself felt, it is almost impossible to prevent the transmission of small-pox by patients who are suffering from this disease during the earlier periods of its course. Small-pox is undoubtedly seldom transmitted from town to town except through tramps or through people who cannot be readily reached for inspection, simply because they do not apply for medical advice until the disease is well developed; whilst in regard to the cases that are not recognised during the earlier stages of the disease, it is probable that these will, from time to time, become more and more numerous from the fact that as there are periods during which

very few cases of small-pox are met with, it is impossible (during these periods) for medical men to make themselves familiar with the exact appearances by which they can accurately diagnose small-pox. It is only during periods of epidemic that medical students and practitioners are able to become familiar with the disease. Efficient sanitary administration is undoubtedly valuable because of the greater resistance that patients who are in good health undoubtedly exhibit against the attacks of all diseases, but it can never be hoped that the directly infectious diseases, such as small-pox, measles, and whooping cough, can be diminished by the most stringent sanitary measures, in the same proportion as typhus and the plague have been, and as cholera and typhoid are being reduced. As regards isolation and quarantine, it is evident, of course, that if every case of small-pox could be isolated at the time that infection took place, and if every case could be detained in quarantine-isolation at the part at which it occurred, small-pox might now be stamped out; but even this position could only have been reached by the aid of vaccination, as without doctors and nurses protected by vaccination or previous attacks of small-pox, it would be impossible to find attendants for these isolated patients. But the whole question of stamping out by these measures without vaccination, is so utterly absurd when the conditions under which the disease is generally spread are taken into consideration, that it is really startling that they should have been suggested as capable of taking the place of vaccination, however valuable they may be as accessory factors. One writer, commenting on the example which Leicester is stated to afford of the value of strict isolation, points out, "that vaccination was carried to nearly every one who was thought to have any chance of coming into contact with the disease, and that nearly every member of the hospital staff gladly accepted re-vaccination." The Commissioners reporting on this point state "that at Leicester, the region of isolation and sanitation, two vaccinated children under ten were attacked, neither of whom died; of unvaccinated children of a similar age, 107 were attacked, of whom fifteen, or 14 per cent., died. Of vaccinated persons over ten years of age, 197 were attacked, of whom two died, or 1 per cent.; of the unvaccinated at a similar age, 51 were attacked, of whom 4, or 7·8 per cent., died." In the case of the hospital staff at Leicester, we have a most striking proof of the efficacy of vaccination. On page 82 of the Report, par. 319, we have the following: "At Leicester, at the end of the year 1892, the staff at the hospital consisted of twenty-eight persons. Fourteen of these had either previously had small-pox, or had been re-vaccinated before the outbreak. Eight others were vaccinated at the time of the outbreak. The remaining six, although they had not previously been re-vaccinated, refused to submit to the operation. During the outbreak there was an addition of twelve to the staff dealing with small-pox cases. These were all re-vaccinated, and none of them contracted small-pox. Out of the twenty-eight, six were attacked by the disease, of whom one died. Five of the persons thus attacked, including the one fatal case (the person in whose case the disease was fatal was said to be of intemperate habits), were amongst the six persons who had refused to be re-vaccinated, though in the case of one of the five consent was afterwards given to the operation, but it was only performed on the day that she showed premonitory symptoms of small-pox. The sixth case, a mild one, was that of a nurse who had been re-vaccinated ten years before." Dr. Gayton gives a similar but even more striking instance in connection with the Homerton Small-pox Hospital. The statistics given in connection with the small-pox ship hospitals in connection with the Metropolitan Asylums Board during the twelve years, 1884–1895, are also very conclusive. Amongst the attendants, varying in number from fifty in one year to 300 in another, there have only been three years out of the whole twelve in which cases of small-pox have occurred. In 1884, there were four cases among 283 attendants; in 1892, two cases among 138 attendants; and in 1893, six cases among 230 attendants. These were in close attendance upon small-pox patients in the hospital ship: all had been re-vaccinated, but in six out of the twelve cases where small-pox occurred it developed within fifteen days of admission to the ship, so that the small-pox infection and the introduction of the vaccine matter had taken place at the same time, or, as in at least two cases, the vaccination had been preceded by the small-pox infection. These are most remarkable figures, and offer evidence that well-vaccinated persons may be brought into very close contact with small-pox patients without running more than a minimal risk of contracting the disease; on the other hand, even the most careful isolation cannot prevent the outbreak of small-pox amongst the unvaccinated, unless the isolation takes place before the disease can be actually recognised, the infectivity making itself felt before the disease can be recognised. The report given by Mr. Allanson Picton and Dr. Collins certainly makes out a strong case for isolation and improved sanitation, but nowhere in it, as we have already said, do they put forward any evidence which can be accepted as proving that these are only of secondary value to vaccination during infancy and re-vaccination at stated periods, and we can quite understand how even Mr. Bright and Mr. Whitbread, along with others of the Commissioners, have been brought to see that it is impossible to contemplate the effect of leaving the whole of the population unvaccinated "without the utmost dismay."

(E) "As to whether any alterations should be made in the arrangements and proceedings for securing the performance of vaccinations, and, in particular, in those provisions of the Vaccination Acts with respect to prosecutions for non-compliance with the Law." In this Section we have the crux of the whole question. The course that the Commissioners have taken affords stronger proof of their belief in the efficacy of vaccination than any other recommendation they could have issued. They believe that the case for vaccination is so strong, that when their report is made public, and when people have had time to digest its contents, especially if the stimulus of alleged martyrdom be removed, that much of the opposition to vaccination will disappear, and that, as in Scotland, where proceedings against parents for the non-vaccination of their children are comparatively rare, the opposition to vaccination will gradually be broken down, and compulsory vaccination will no longer be necessary. Going on the principle that failure to comply with the vaccination laws is often the result of carelessness and desire to avoid trouble, although in justification of this carelessness an objection to vaccination may afterwards be developed, the Commissioners suggest that it should be necessary to take at least as much trouble to escape vaccination as to allow the child to be vaccinated. Conscientious objectors are to be allowed to make a declaration before a magistrate; this would be still more effective were it necessary to go before the magistrate in open court. The exact nature of the recommendations of the Commissioners, however, is a matter of very slight importance, as the general impression produced by this report must be overwhelmingly in favour of vaccination; and those who maintain, or rather did maintain, that the Commissioners were of opinion that vaccination was a failure, had either not read the report or had intentionally misunderstood it. As we have pointed out, of those who are against compulsory vaccination, even in the modified form suggested by the majority of the Commissioners, two are still so convinced of its efficacy that they sign the general report; and the other two, although maintaining that isolation and improved sanitary administration are sufficient to cope with the disease, nowhere lay down as a proposition that vaccination affords no protection against small-pox. After a careful perusal of the report we are convinced that, although this Commission has taken seven years during which to sift evidence and make its report, it has, both from the momentous issues at stake, and by the judicious nature of its finding, been thoroughly justified from beginning to end, and that the report will be accepted as one of the best ever presented to our, or to any other, Parliament.

SOME ENGINEERING ADVANCES IN SIXTY YEARS.[1]

WE meet this evening under peculiar circumstances, some of which are of much interest to every member of the empire, and others are specially appertaining to the Institution. These circumstances seem to me to mark the year 1896 as an epoch, at which your President may offer to you some remarks which will be not strictly a review of any of the various recent feats of engineering, but rather a retrospective survey of the general progress with which engineering has been and is intimately connected, and a consideration of some matters past, present, and future, which appear to me to touch closely the interests of us all as members of the profession.

The material advances which this country has made during the Queen's reign are so remarkable, and have depended so

[1] Abstract of the presidential address delivered before the Institution of Civil Engineers on November 3, by Mr. J. Wolfe Barry, C.B., F.R.S.

much on engineering developments and progress, that I think we, as members of that profession, may at such a time as this survey with profit the period covered between the accession in 1837 and the present time from that point of view, and endeavour to recall some of the differences in various circumstances which have so greatly affected the interests of the population.

No one can deny that these years constitute the most important period yet known of engineering, or that the work of engineers during this period has had most far-reaching effects upon the material interests of the inhabitants of these islands, as indeed of the world at large—whether those effects have been produced by improved means of inter-communication by land and sea, of sanitation, or of labour-saving appliances.

The rapid growth of towns has occasioned a demand, especially within the last thirty or forty years, for urban railways, tramways, bridges, subways, improved pavings, and other means for facilitating intercourse between the different districts of our large towns. It has been the cause of a great development of additional sources of water supply, of improved sewerage, of new means of lighting by gas and electricity, and, above all, has necessitated that minute and careful study of the laws of sanitation which has produced most remarkable results on health and longevity.

Although a short time prior to the Queen's accession, the Stockton and Darlington, the Newcastle and Carlisle, the Liverpool and Manchester, and some isolated railways had been opened and worked by locomotives, and several railways had been worked by horses before the introduction of locomotives, none of the main arterial lines had been opened; and it was not till 1837 that the Grand Junction Railway connected Liverpool with Birmingham, nor till 1838 that the London and Birmingham line was completed. The first through line from London to Scotland was not available for traffic till more than ten years after the Queen's accession, and was then dependent on ferries across the estuaries of the Forth and Tay. Practically speaking, therefore, the railway system of these islands, which was many years in advance of other countries, has been developed in the Queen's reign.

At the date of the accession, though an American ship called the *Savannah*, with small auxiliary engines, had crossed the Atlantic in 1819 in about a month, such a voyage, if attempted by vessels entirely or mainly dependent on steam, was considered by high authorities to be a mathematical impossibility. It was further held that no steamer could face the monsoon in the Red Sea, and, practically speaking, steam navigation was looked upon as only suitable for short voyages across the narrow seas, or for river navigation. In 1838 the *Great Western*, of 2300 gross and 1340 registered tonnage, designed by our past Vice-President, I. K. Brunel, demonstrated for the first time the possibility of the establishment of a regular service of steamers across the Atlantic, and the *Great Western* ran regularly between Bristol and New York for many years, the journey occupying about fourteen days. In 1845 the *Great Britain*, of 3443 gross and 2984 registered tonnage, which was the first large ocean-going steamer in the mercantile marine which was built of iron, and to which the screw-propeller was applied, also designed by Brunel, marked a further important step in advance, and she crossed the Atlantic in about twelve days. By 1840, steamers were overcoming even the dreaded monsoon in the Red Sea and Indian Ocean. Nowadays, as every one knows, the journey to New York occupies a little over five days, at an average speed of 21 knots an hour by vessels of 12,000 tons, with engines of 30,000 h.p.

The mining industry, which again is specially an engineering subject, and on which the prosperity of our country mainly depends, has during the Queen's reign made very great strides. In 1854, the total quantity of coal produced was 65 millions of tons, equal to 2·34 tons per head of population, and in 1895 the total quantity had increased to about 200 millions of tons, equal to 4·73 tons per head of population. The increase of production is continuous, and probably points to increased exports as well as to increased consumption in manufactures or traction. This large quantity of 200 millions of tons annually excavated is difficult to realise. If we assume a thickness of coal *in situ* of 6 feet, the total quantity excavated now annually would occupy nearly 21,000 acres, which is equal to twenty-five times the area.

Prior to 1851 there was no submarine cable across the Channel, none to the United States till 1858, nor to India, Australia, or South Africa till 1865, 1872, and 1879 respectively. Nowadays the mileage of submarine cables is 162,000 miles, the capital employed in them is 40 millions, and the total number of foreign and colonial telegrams is about seven millions annually, without reckoning those that are sent by the submarine companies without the intervention of the Post Office.

This brief retrospect gives some idea, however faint and imperfect, of what has been done by engineers during the past sixty years in facilitating inter-communication between individuals in this and other countries, and in the distribution of produce.

Let us now glance shortly at some of the statistics of the work of the sanitary engineer, whose work affects the duration of human life and the enjoyment of health of every individual. The mean death-rate of London for the various decades from 1840 up to 1870, when the main intercepting sewers of the metropolis were brought into use, was 24·4 per thousand. In 1880 it was reduced to 22·5, and it is now 19·5. This reduction of almost five per thousand, which means a saving of life in London alone of 22,000 individuals annually, is very largely due to the work of the sanitary engineer, though, of course, it is also to be partly accounted for by better wages, better organisation, and better medical education.

Though much of the reduction of the death-rate in towns may properly be attributed to improved sewerage, I by no means think that we ought to look to that cause as being of equal importance to an ample supply of good water. In this direction immense progress has been made during the Queen's reign, and it seems almost impossible for us now to conceive London in its condition of 1837, honeycombed with cesspools, and largely supplied with water either from surface wells, or from the Thames at Battersea or Hungerford.

Though gas for lighting was invented and began to be used prior to the accession, its cheapness and universal application to towns and large villages mark another engineering success of the reign of our Queen, and lately its application to heating purposes is a further most important step.

I have spoken of the work of engineers in railway and steamship transport, in the development of postal, telegraphic, and telephonic inter-communication and in sanitation. These indeed are important successes, but what a record there is for our profession in other labour-saving appliances—in the improvements of spinning and weaving machinery, in lace-making, in the working of iron and steel, in the invention and perfecting of hydraulic machinery—the work and success of our valued Past-President, Lord Armstrong. Hydraulic machinery has done such wonders for the use and convenience of man in every department of manufacture and trade, that it is almost impossible to conceive how even the limited amount of work of our forefathers could have been carried on without such convenient means of the transmission of power as the accumulator and high-pressure water afford.

Again, what a field has been occupied and cultivated within even the latter half of our sixty years by the electrical engineer! This subject is full of the greatest interest, but it is sufficient by itself for an address such as this, and I have no doubt it will be fully dealt with by him whom I look forward to welcoming as my successor. I have spoken shortly of telegraphs and telephones, and I can only further allude to and note the great strides already taken in the transmission of electric energy, whether it be used for traction, lighting, heating, actuation of motors, smelting of refractory metals, welding, or for electrolysis, such as in the production of aluminium or in various other branches of trade.

With regard to traction, which is a seductive subject for enlargement, I will only remark that electric traction has now passed through the experimental stages, and may be looked upon as an accomplished idea. Without entering on the question of its universal adaptability for railways in general, we can see that indisputably it is eminently fitted for any underground railway. We have the facts that the South London Railway and the Liverpool Railway have been and are being worked electrically at this moment; that a French railway company have been working a full-sized train for months between Paris and Mans by an electrically actuated locomotive, though the electricity is generated on that same locomotive, and not conveyed by a conductor; that the Baltimore and Ohio Railway Company of America has constructed and worked an electric locomotive weighing about ninety tons, actuated by electricity conveyed to it by a conductor; and that thousands of miles of tramways are worked by the same means. No doubt the application of elec-

tricity to the working of heavy trains under the exigencies of such traffic as the Metropolitan and District Railways will involve some new problems and require much consideration; but for myself I think the time has come for the work to be faced, and I am persuaded that, large as the necessary capital required may be, it will be well spent.

Before leaving the subject of the present developments of electricity, I may draw attention to the work recently inaugurated at Foyers or Loch Ness for the employment of water-power in the production of electricity for the manufacture of aluminium out of bauxite. For the production of aluminium successfully by this process with commercial success, a great deal of power must be available at a cheap rate, and water-power appears to be the only available source for such a purpose. The rainfall in this country, especially on the west coast, provides a most important agent if it can be stored cheaply at a high level, and both these desiderata are possible at Foyers, as also at other sites on the west coast. When we know that the rainfall at such places as Fort William, Ballacludish, Cumberland, and North Wales, varies from 6 feet to 7 feet per annum, and that the configuration of the country renders storage peculiarly easy, we can see that a great future may remain for the use of water-power, not only in the manufacture of aluminium, but also of acetylene and other products which may in the future attain to much importance. At Foyers the working head of water is 350 feet, and the power already developed is 3608 h.p., at an estimated cost per h.p., per annum, which is only 25 per cent. of the cost of steam-power where coal is cheap. Of course this is merely in a humble way what has been done by harnessing Niagara for commercial purposes; but this application of the forces of nature seems to me to have much promise for the future in this country.

Another most interesting subject of contemplation is the work of the engineer as applied directly to domestic life. I suppose that the invention of the lucifer match—not an engineering but chemical achievement—slightly before the beginning of the reign, but brought to mature development within its early years, was perhaps the greatest domestic boon of the century. An old friend of mine (my fishing ghilly) has described to me how, about 1839, he bought, in a then remote part of Scotland, three lucifer matches for sixpence, and exhibited them to his friends and neighbours, who naturally looked upon them with amazement and some amount of distrust as not altogether canny. The instant availability of light and heat was a stride of the greatest importance, and it is impossible to overrate it as a priceless boon for humanity. In the same way three most important home engineering feats, viz. the invention of the sewing-machine, the adaptation of machinery to the manufacture of watches and clocks, and the invention of the safety bicycle, touch and will continue to touch the home life of more individuals directly and intimately than many other engineering developments of the epoch.

Approaching now the circumstances of the present year, I think a subject of special interest at the present moment to engineers is that new departure which has been authorised by Parliament, and which may have an important bearing on the subject of intercommunication to which I have alluded—I mean the Light Railways Act, and what may be called the Auto-Motor Emancipation Act of last session.

I have little doubt that light railways will, in many districts, be of great utility, and I earnestly hope for, and fully expect, at the hands of the Commissioners appointed, a well-considered policy. Much will depend on the inauguration of the system on sound lines. I hold strongly that light railways should in all cases, other than where they will be independent approaches to a port or to a market, be of the same gauge as the standard gauge of the country. The traffic on these lines (with the above exceptions) must be dependent on the trunk or parent line, and in the nature of things will be small in each individual case.

A very important subject for consideration also in connection with the Light Railways Act, and in itself, is the future of auto-motors as applied to the light traffic, whether of goods or passengers, to be accommodated by the proposed light railways: and no engineer can read the accounts of the results attained by auto-motors, or have seen the machines in operation, without recognising their great promise for the future.

The astonishing thing is that, seeing that about the date of the Queen's accession Hancock ran his steam omnibuses regularly between Paddington and the city, and that Gurney and Scott Russell also ran auto-motors commercially about the same time, and that the subject has engaged the attention of engineers from that time to the present, resulting in various most promising auto-motors, it should be reserved for 1895 and 1896 to show so many practical vehicles. One would have thought that the force of invention, backed by public opinion, would have been sufficient before now to have compelled an alteration of the ridiculous regulations of the Acts of Parliament now happily repealed.

Without for one moment decrying the status of the able engineers who exercised their craft prior to 1837, I think it may be said that the Queen's reign has, practically speaking, witnessed the birth of engineering as a profession of a most important character, and with a great future, fulfilling duties of extreme delicacy, and bearing perhaps more responsibility in respect of life and expenditure than is supported by any other calling.

I have enlarged on the subject of the exploits and triumphs of the engineering profession, not in a spirit of boasting, as the representative for the time being of a profession to which I am proud to belong, but with the view of pointing out the dignity of our calling, and the burden laid upon us thereby, as members of this great Institution, of not letting that dignity suffer any loss or disparagement in the years to come.

In connection with the subject of the education of engineers, it is a matter of much interest to us to know what is the instruction given to engineers of other countries, and the guarantees that it has been more or less assimilated by those who are members of kindred institutions. I will only say here that I have made it my business to gain, through our Secretary, much recent information on these points, which were also investigated in 1870 at the request of the President and Council by our Honorary Member, then our Honorary Secretary, Dr. Pole. To enter into these particulars in such an address as this is impossible, and I must content myself by saying that in France, Germany, Austria, Russia, Belgium and Holland, the greatest attention is paid by the State to a strict scientific training, and that the utmost care is taken to see that all candidates for employment as engineers are, so far as education is concerned, thoroughly equipped for the work which may lie before them.

I see no proper way to ensure the same results being attained in this country except through the instrumentality of this body, which is the representative of the profession here; and I venture to think that if this Institution is to retain its present honourable position as the acknowledged head of the engineering profession of Great Britain, and of Greater Britain, we should see that any credentials or degrees conferred by us are based on undoubted qualifications.

BOTANY AT THE BRITISH ASSOCIATION.

AFTER the delivery of the presidential address by Dr. D. H. Scott, F.R.S., an interim report was presented on the method of preserving and displaying botanical museum specimens.

An important new feature at this year's meeting was an address by the Director of the Royal Gardens, Kew, on the geographical distribution of plants. The lecture was primarily intended for those possessing a general interest in botanical science, rather than for specialists. It is hoped that the success of the experiment will lead to a continuance of such addresses at future meetings of the Botanical Section. Another interesting feature was the prominence given to two important subjects which have been matter of discussion and research for some years—the ascent of water in trees, and the problems of cell-division.

Mr. Francis Darwin, F.R.S., in opening the discussion on the former subject, contributed a paper in which the present state of our knowledge of the ascent of water was lucidly set forth, and treated from a critical standpoint. Prof. Marshall Ward discussed several of the questions raised, from a botanical aspect, with special reference to capillarity and imbibition, and particularly the structure of wood. In addition to various botanists, Prof. Fitzgerald and Dr. Joly, of Dublin, took part in the discussion, and dealt with the question mainly from the physical side. It is probable that a fuller account of the discussion will be given in a forthcoming number of the *Annals of Botany*. Mr. Darwin dealt with the subject under two main heads—the *path* of the ascending current in trees, and the *force* which produces the ascent of the water. Attention was called

to the necessity of a complete study of the minute structure of wood in relation to the modern theories. The concluding words of the opening address may be quoted *verbatim* :—"It is at least a hopeful fact for Messrs. Dixon, Joly, and Askenasy that we cannot point to anything in the anatomy of wood which is absolutely inconsistent with their views. Whether we are friends or opponents of Messrs. Dixon, Joly, and Askenasy's theory, the broad facts remain that water has the power of resisting tensile stress, and that this fact must henceforth be a factor in the problem. There are difficulties in the way of our authors' theory, but it is especially deserving of notice that many of these difficulties are equally serious in the case of any theory which excludes the help of the living elements of the wood, and assumes a flow of water in the tracheals. The authors have not only suggested a *vera causa*, but have done so without multiplying difficulties. There is, therefore, a distinct balance in their favour. Huxley, quoting from Goethe, makes use of the expression *thätige Skepsis*. It is a frame of mind highly appropriate to us in the present juncture, if we interpret it to mean a state of doubt whose fruit is activity, and if we translate activity by experiment."

Prof. Vines, F.R.S., drew attention, in the first place, to a paper of his, recently published in the *Annals of Botany*, giving an account of a number of experiments on the suction-force of branches. He had been under the impression that the results obtained were independent of the action of atmospheric pressure —that they were solely indications of tensile stress exerted by the transpiring branch upon the water in the apparatus ; but now he had reason to believe that they were, as a matter of fact, affected by the atmospheric pressure. Hence these results are not different in kind from those of other observers, but are comparable with them. The apparatus which he employed is, however, very useful, on account of its sensitiveness and simplicity, for purposes of demonstration.

The observations in question brought out two important facts : (1) that a high suction-force can be developed by branches which have been deprived of their leaves ; and (2) that this suction-force is not dependent upon the life of the branch. He then proceeded to give an account of subsequent observations made with dead hazel-branches (pea-sticks), which had been found to develop considerable suction-force amounting, in one case, to 19½ inches of mercury with a stick 18 inches long. He concluded by expressing the opinion that, in recent attempts to explain the mechanism of the transpiration-current, the part played by the "imbibition" of the cell-walls had been underestimated ; and urged that what was especially requisite for further advance, is a more complete investigation of the physical properties of a dead piece of stick.

The second discussion, on some current problems connected with cell-division, was opened by Prof. Bretland Farmer, who gave a very complete account of the present position of cell-division problems, before a joint meeting of Sections C and K. In reference to the centrosome question, Prof. Farmer spoke as follows :—

"Few people are agreed as to what its (the centrosome) very nature actually is, and perhaps still fewer as to the part which it plays in the cell. Some regard it as the active agent in bringing about nuclear division, whilst others believe it to be a transient structure, called into existence by the forces which are at work during karyokinesis. The occurrence and behaviour of centrosomes during karyokinesis (nutosis) require a comparative treatment. Whilst it is quite possible that in the cells of some organisms, the centrosome may possess a marked individuality, it does not therefore necessarily follow that it must occur universally, or that it is concerned, as a principal, with the process ; and this latter remark applies even to those instances in which it appears most prominently."

Profs. Minot, Zacharias, Hartog, and others, took part in the discussion. An important contribution, bearing directly on this subject, was made by Miss Ethel Sargant in a paper entitled "On the heterotype divisions of *Lilium Martagon*." Her work may be briefly summarised as follows. There are two series of nuclear division in the life-history of *Lilium Martagon*, which exhibit twelve chromosomes in place of twenty-four. The preparations made by Miss Sargant include the whole oögenetic series and the first three divisions of the spermatogenetic series. The second and third divisions in both are precisely similar to vegetative nuclear divisions except in possessing only half the number of chromosomes. They are called *homotype*.

The first nuclear division on either side is called *heterotype*, because the process of karyokinesis differs from that of the vegetative nucleus. Miss Sargant dealt with the distinguishing features of the latter heterotype divisions.

THALLOPHYTA.

Prof. Magnus, of Berlin, gave an account of some recent observations on the Chytridiaceous genus *Urophlyctis*. The author maintained the genus *Urophlyctis*. He described the development of the species *Urophlyctis Kriegeriana*, occurring in *Carum carvi*, established by him some years ago, and showed that its spores are formed by the conjugation of two cells, arising from different filaments, and that the development of the fungus takes place within a single cell of the host, namely, the central cell of the gall produced by it, which is of limited growth. The author proved that the fungus observed by Trabut in Algiers, which causes large swellings on beetroots, also belongs to this genus *Urophlyctis*. Prof. Magnus proved that its spores are likewise formed by the conjugation of two cells, arising from different filaments, exactly as in *Urophlyctis*.

Mr. Vaughan Jennings contributed a note on *Corallorhiza innata*, R.Br., and its associated fungi. Without being able to speak of his conclusions as in all cases definitely established by proof, the author thus summarised his results.

"So far, then, as this district (Davos Platz) is concerned, it seems that the 'mycorhiza' of *Corallorhiza* is a hymenomycete, and commonly an agaric ; and that certain species of *Tricholoma* and *Clitocybe* are those commonly observed. The only other forms yet noted in proximity to *Corallorhiza* are *Cortinarius subferrugineus*, Batsch., and *Mycena umbellifera*, Sch., but further evidence with regard to these is at present wanting."

Mr. Vaughan Jennings also gave an account of a form of *Schizomycetes*, for which he proposed the name *Astrobacter fenestrati*.

Mr. Coppen Jones contributed some observations on the so-called tubercle *Bacillus*. He expressed the opinion that there are several considerations which tend to modify our views with respect to its biological status. The facts he brought forward favoured the view that the so-called "tubercle bacillus" is really a stage in the life-history of some higher form of fungus with a definite mycelial growth. From a systematic point of view, it cannot be regarded as coming within any definition of the genus *Bacillus*, and it is suggested that a more appropriate name would be *Tuberculomyces*. Whether the change in our view as to the real nature of the tubercle fungus will in the future be of any diagnostic value it is impossible to say, as comparatively few cases showing the filamentous growth have yet been observed ; but there is some evidence in support of the idea that the hyphal type may be correlated with more chronic stages of the disease, where actual tissue destruction is relatively slight.

Mr. W. G. P. Ellis contributed an account of the life-history of a fungus which is the cause of a parasitic disease in the Liverwort *Pellia epiphylla*. A disease appearing on and spreading centrifugally over a pan of *Pellia* was investigated during the summer of 1896. The author was led to regard the fungus as the conidial phase of an Ascomycete, similar to, if not identical with *Ascotricha*, the conidial stage of a *Chætomium*.

Prof. Chodat, of Geneva, communicated an extremely interesting paper of far-reaching importance on the polymorphism of the green algæ, and the principles of their evolution. The green algæ may be divided into two distinct groups, the *Euchlorophyceæ*, and the *Siphoneæ*. In the former a true cell-division takes place, while in the latter the thallus is non-cellular. The starting-point in the evolution of the *Euchlorophyceæ* is very likely the *Palmellaceæ* (including the genera *Tetraspora*, *Palmella*, and *Apiocystis*). Observations show that no clear boundary line can be drawn between the different groups and the *Palmellaceæ*, from which they are supposed to be derived. The *Volvocineæ*, for example, agree very closely with the *Palmellaceæ* in the structure of the cells, but in these the resting stage is only transient. In this non-motile condition obtained by culture, they cannot be distinguished from the latter. In another direction the *Protococcaceæ* can be derived from the *Palmellaceæ* by the prevalence of the sporangial condition. In some species or genera the single-celled sporangium produces zoospores, but in the course of evolution these are replaced by the non-motile spores, when the mother cells or sporangia have a definite form as in *Scenodesmus* and *Raphidium*.

In certain forms of *Pleurococcus vulgaris* a production of zoo-

spores occurs, and in others these are replaced by non-motile spores. In this case, as in others, it is easy to observe that a true difference between the so-called cell division and free cell formation (Al. Braun) does not exist; the latter being only the result of an early or late dissolution of the septa.

The homology of the sexuality of *Coleochæte* with the *Archegoniatæ* is only apparent. In none of the green algæ (*Euchlorophyceæ*) can an archegonium or antheridium be recognised. The genus *Aphanochæte* clearly shows that the affinity of *Coleochæte* is with the *Chlorophyceæ*, and not with the *Archegoniatæ*. A fuller account of Prof. Chodat's paper is to appear in the *Annals of Botany*.

Prof. Zacharias, of Hamburg, gave an account of his researches on the histology of the blue-green algæ. In each cell there is a central colourless portion surrounded by protoplasm containing colouring matter. The protoplasm, when treated with reagents, reveals a spongy structure. In the surface, or occasionally outside the central portion, there occur granules which agree in certain reactions with the chromatin of the nucleus of other organisms. To these granules Zacharias has given the name of "central substance." More recent investigations have made it doubtful whether the central substance contains nuclein like the chromosomes. It is probable that the central body of the spore contains glycogen. In the cell protoplasm there occur granules different from the central substance. Cell-division occurs without the karyokinetic figures.

PTERIDOPHYTA, &c.

A paper of exceptional importance was read by Mr. Lang, on some peculiar cases of apogamous reproduction in ferns.

In order to ascertain to what extent apogamy in *Nephrodium filix-mas*, Desv., is correlated with the cresting of the fern plant, from which the spores were derived, the author made cultures of normal and crested forms. Of the three cultures of normal forms one was unsuccessful; one of the others was exclusively apogamous, while the other reproduced itself in the ordinary way. Seven crested varieties were sown; five of these were apogamous, and the other two normal.

Cultures were also made of crested varieties of other species. In all in which young plants were produced their development was at first normal. After the cultures had continued for nine months young plants, developed apogamously, were found in *Scolopendrium vulgare*, *Athyrium filix fœmina*, and *Aspidium aculeatum*, var. *angulare*.

Unfertilised prothalli of *Scolopendrium vulgare* formed a cylindrical, fleshy prolongation of the midrib, the tip of which became in time covered with ramenta, and was continued directly as the axis of the young sporophyte. Archegonia were present just below the ramenta.

In some prothalli of a fern from Mr. Druery's collection, which was labelled *Lastrea dilatata*, var. *cristato-gracilis*, a similar prolongation of the median region was found. Upon this sporangia were borne, sometimes singly, in other cases grouped together so as to resemble a sorus. The sporangia had a well-developed annulus, which sometimes showed the characteristic reddish-brown thickenings of the wall. The prolongation on which the sporangia were situated bore archegonia and antheridia, which sometimes intervened between two groups of sporangia. Its prothallial nature was, therefore, beyond doubt. The sporangia were borne on prothalli on which no trace of a young sporophyte could be detected.

Prof. Bower, F.R.S., contributed a paper on the enumeration of spore mother-cells and spores as a basis of comparison of ferns. The author brought out, in a striking manner, some interesting points of comparison between different fern types. He gave in a tabular form the results of computation of the number of spores per sporangium in representatives of various ferns, and also of sporangia and spores per sorus. These brought out distinctly the fact that the potential output per sporangium, as estimated by the number of spore-mother cells, varies very greatly among Leptosporangiate ferns, being only 16 in *Ceratopteris*, while in *Gleichenia* the number may be about 1400; *Aneimia* and *Osmunda* showing, respectively, about 128, and over 500. The further fact that *Gleichenia* produces an output virtually equivalent to that of *Angiopteris*, is specially interesting as showing that no numerical gulf lies between the Leptosporangiate and Eusporangiate ferns.

Remarks were also made on the parallelism of complexity of sporangia and antheridia in various homosporous Pteridophyta.

After the papers by Prof. Chodat, Prof. Bower, and Mr. Lang had been read, a discussion took place, which had special reference to the general question of alternation of generations in plants, which had been treated at some length by Dr. Scott in his opening address. In reply to arguments advanced by Dr. Scott, and relating especially to the examples of apogamy described by Mr. Lang, Prof. Bower expressed the opinion afresh that both apogamy and apospory are to be looked upon as abnormalities, which are not a proper subject for strict morphological argument; moreover, both are susceptible of a physiological explanation, as substitutionary growths. The argument from apospory, as evidence of homologous alternation, involves the fallacy that parts which, under unusual circumstances, can be induced to undergo similar development are of similar origin.

If such abnormalities as Mr. Lang describes be used for argument, the complete jumble of succession would allow of almost any view. The opinion was expressed by Prof. Bower, on the general question, that neither by the description of these abnormalities, nor by the other arguments advanced by Dr. Scott, is the case for homologous alternation made out. The green algæ can at most be used as examples of how alternation may have originated.

Dr. Scott then replied to Prof. Bower's criticisms.

HIGHER PLANTS; PHYSIOLOGY, ANATOMY, &c.

Prof. Casimir de Candolle, of Geneva, contributed some exceedingly interesting notes on latent life in seeds. The author gave an account of some experiments, recently carried out, on the power of germination of seeds exposed for different periods to a low temperature. He also recorded striking instances of the development of normal seedlings from seeds which had been kept for a great number of years. Robert Brown obtained perfect seedlings from seeds of *Nelumbium speciosum* more than a century old. Plants buried under rubbish heaps collected by the Greeks, have been found to develop and bear flowers from seeds which must have been at least fifteen hundred years old. To test the condition of a dormant seed, M. de Candolle exposed the seeds of several plants to a temperature too low to admit of the continuance of the process of respiration. Seeds of corn, oats, fennel, *Mimosa pudica*, and *Gloxinia*, &c., were exposed for 118 days to a temperature of 40° F. below zero. The experiments were carried on at Liverpool in refrigerating machines, in which during eight hours each day the average temperature recorded was – 40° F., and occasionally far lower. Nearly all the seeds of corn, oat, fennel, and a great many of the *Mimosa* seeds germinated. The conclusion to be drawn from the experiments seems to be, that in resting seeds the protoplasm is not actually living, but has reached a stage of inaction in which, although not dead, it is endowed with potential life. In other words, protoplasm in resting seeds is not analogous to a smouldering fire, but rather to those chemical mixtures made up of bodies capable of combining under certain conditions of temperature and illumination.

Prof. Marshall Ward, Dr. Scott, and others discussed several important points suggested by Prof. de Candolle's paper.

Prof. Trail, F.R.S., gave some account of his recent observations on the floral deviations in some species of *Polygonum*. The genus has long been known to show considerable departures from the arrangement and number of parts accepted as most typical (Per. 5. St. 5 + 3, C. $\frac{3}{2}$), such as is found in *P. convolvulus*.

A comparison of different species shows that while each varies, so as in the more variable species to cover almost the whole range observed in the genus, each shows a tendency to certain lines of variation. These tendencies are more alike usually in the more nearly allied species, so as to correspond in the main with the groups based on habit, and they lead from group to group.

The modes of variation commonly observed include almost all the recognised modes of departure from floral symmetry. They affect all the whorls. The *perianth* in some species is very constant. In others it habitually shows cohesion of two or more segments, or abortion in different degrees, or suppression of one or two (usually the inner) segments. Chorisis of a segment is less frequent. Enations from one or more segments are frequent in certain species, rare or absent in others. The *outer stamens* often show cohesion of the two in each pair, varying from the slightest union of the bases of the filaments to absolute union of even the anthers. Abortion (in all degrees to complete suppression) of one or more stamens is not rare. The *inner stamens* seldom show cohesion (except in *aviculare* and its

allies) with stamens of the outer whorl. Abortion is very frequent, and in certain species (*amphibium*) this whorl has completely disappeared.

Miss Lily Huie contributed some observations on the changes in the tentacle of *Drosera rotundifolia*, produced by feeding with egg albumen.

In unfed leaves fixed in watery picro-corrosive (sp. gr. 1·020) and stained with Eosin-Toluidin blue, the apical and lateral glands of the first or outer layer, and also all the cells of the second or middle layer, show a deep-blue cytoplasm, with nuclei possessing little chromatin proper, but large nucleoli and a granular nucleoplasm. Within one minute after feeding the blue cytoplasm becomes purple; after one hour it is greatly vacuolated and reddish purple; after twenty-four hours the blue material has disappeared, and only a few strands of a pink cytoplasm are to be seen. The nucleus after feeding loses the granular cytoplasm, the nuclear chromatin segments enlarge enormously, reminding one of the early stages of mitosis. The nucleolus has lost its red chromatin, and is not easy to see.

Recuperation of the cytoplasm is the result of nuclear activity, for the chromosomes enlarge during the period preceding the appearance of the granular nucleoplasm, which latter in every respect resembles the granular deposit of cytoplasm in immediate contact with the outer surface of the nuclear membrane.

Dr. Morris, C.M.G., contributed a note on the singular effect produced in certain animals in the West Indies, by feeding on the young shoots, leaves, pods, and seeds of the wild tamarind or Jumbai plant (*Leucæna glauca*, Benth.). The wild tamarind of Jamaica, and the Jumbai or Jumbie of the Bahamas, is commonly found along roadsides and in waste places in tropical America. It presents the appearance of a weedy-looking *Acacia*, and belongs to the tribe *Eumimoseæ* of the N.O. *Leguminosæ*. It occurs in the West Indies, Bahamas, Demerara, Brazil, Peru, gardens of South Europe and North Africa; widely found in tropical Africa, East Indies, Ceylon, Mauritius, Java and China.

The author described the plant as being distinctly encouraged in the Bahamas as a fodder plant. The people were fully aware of the singular effect it produced on horses, and added that it also affected mules and donkeys. Its effect on pigs was still more marked. These animals assumed a completely naked condition, and appeared without a single hair on their body. Horses badly affected by Jumbai were occasionally seen in the streets of Nassau, where they were known as "cigar-tails." Such depilated animals, although apparently healthy, were considerably depreciated in value. They were said to recover when fed exclusively on corn and grass. The effects of the Jumbai on horses, mules, donkeys, and pigs were regarded as accidental—due to neglect or ignorance. The seeds probably contain the deleterious principle in a greater degree than any other part of the plant. The active principle in *Leucæna glauca* has not yet been investigated. There is abundant material at hand for this purpose in almost every part of the world. It is probable that the active principle may consist of a volatile alkaloid somewhat similar to that found in *Lathyrus sativus*.

In *Leucæna glauca* we possess a plant with singular properties. It is a vegetable depilatory of a very decided character. No other plant appears to produce exactly identical results.

Mr. Scott Elliot read a paper on the influence of habitat upon plant-habit. The author gave the results of an attempt to tabulate and compare the habits and habitats of the *Ranunculaceæ*, *Papaveraceæ*, &c., in the Kew and British Museum herbaria. The tables exhibited illustrated the dependence of habit upon habitat in 230 plants. In conclusion the author anticipated the objections of those who hold the original hypothesis of Prof. Weismann (that acquired characters can by no means be inherited), by pointing to the most recent publication of this writer, wherein use inheritance of a kind is admitted.

Dr. Wilson exhibited a series of excellent photographic lantern slides illustrating his numerous experiments on hybridisation in Passion flowers and Albucas. The first paper, on a new hybrid Passion flower, dealt with a cross between *Passiflora Buonapartea* and *P. Caerulea*, the latter being the pollen-parent. The former has a quadrangular winged stem, and the leaves are elliptical in outline; the latter has a cylindrical stem, and the leaves five-lobed. The stem of the hybrid exhibits many intermediate characters, and the leaves are three-lobed. The presence of a group of glands terminating the coronal filaments was shown on the screen. The glands are present in the seed-parent, but not in the pollen parent, and in the hybrid they appear in reduced number.

In a further communication, dealing with observations on hybrid Albucas, Dr. Wilson exhibited a large series of illustrations from nature, showing the effects of hybridisation on the bulbs and flowers of these plants. He described a new species, named by him *A. prolifera*. This species is characterised by producing remarkable lateral outgrowths which carry young bulbs, while it also bears numerous obscurely-stalked basal bulbils.

Mr. Gwynne-Vaughan gave an account of his investigations on the arrangement of the vascular bundles in certain *Nymphaceæ*.

Mr. Keeble described certain observations on the *Loranthaceæ* of Ceylon, relating to the emergences on the embryo of *Loranthus neelgherensis*, and to the mode of penetration into the host.

Fossil Plants.

Dr. D. H. Scott, F.R.S., gave an account of some researches on certain Carboniferous fossils referred to *Lepidostrobus*.

Mr. A. C. Seward contributed notes on a large specimen of *Lyginodendron*, based on the examination of specimens in the British Museum. He proposed to designate the species *L. robustum*.

Mr. Seward also gave an account of a new cycad from the Isle of Portland.

Dr. Woodward lately obtained an exceedingly fine specimen of a cycadean stem from the Purbeck beds of Portland, which is now in the fossil plant gallery of the British Museum. The stem, which is probably the largest known, has a height of 1 m. 18·5 cm., and measures 1 m. 7 cm. in girth at the broadest part. A striking feature of the specimen is the conical apical bud enclosed by tapered bud scales, bearing numerous ramental outgrowths on the exposed surface.

REPORT ON TECHNOLOGICAL EXAMINATIONS.

THE Report, just issued, on the work of the Examinations Department of the City and Guilds of London Institute, is a noteworthy document. The functions of this department of the Institute extend beyond those of an ordinary Examining Body. Its efforts have been directed for many years towards encouraging, in different ways, sound technical instruction; and the aim of the Committee has been rather to secure for artisan students systematic teaching, than to increase the number of candidates for examination. Unfortunately, such students are often quite unprepared to receive technical instruction.

Several of the Examiners refer to the defects of the earlier education of the students, and some surprise is expressed that the candidates spell so badly and experience such difficulty in expressing what they know in words. The Examiners in plumbers' work complain that very few of the candidates knew how to work out a simple geometrical problem, and that in those elementary principles of science which underlie plumbers' work, a very small proportion of the candidates appear to have received any adequate instruction. Among engineering apprentices, a large number of candidates appear to have attended science classes; but in the subjects of weaving and spinning, and in most other subjects, the number is very small. The Committee of the Institute have consequently come to the conclusion that the principles of science should be presented to the artisan student in a form bearing more directly upon the trade in which he is engaged, than is possible when the elements of any one branch of science are taught to a large class of students occupied in different pursuits. They have accordingly added to their programme a course of instruction to be taken before certain technical subjects. This difficulty as to inadequate preliminary knowledge is met with all over the country, and is a constant cause of failure in many branches of the work of Technical Education Committees.

Another difficulty widely experienced is to find competent teachers for trade classes. This arises from the combination of qualifications required in such teachers. It is desirable that they should spend sufficient time at their trade to have become skilful workmen; they must have some knowledge of scientific method, besides having received a fairly good general education. The Committee think that facilities in the way of scholarships should be offered by County Councils to intelligent workmen, to

enable them to spend two years at a Central Technical School, in order to acquire the necessary knowledge of scientific principles and some acquaintance with methods of instruction. Whether the "intelligent workman" would afterwards be content to pass his days in the workshop, and his evenings in the class-room, is another story. But however this may be, the intentions of the Committee are good, and we should be sorry to say anything which would tend to depreciate the admirable efforts they are making to improve the condition of technical education in this country. Mr. G. Matthey, the Chairman of the Committee, and Sir Philip Magnus, the Superintendent of the examinations, deserve the thanks of every one interested in the development of our industries for their organisation of knowledge which lies at the root of such developments.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Dr. Glaisher, F.R.S., has been appointed Chairman of the Examiners for the Mathematical Tripos, Part II. of 1897. Mr. J. G. Leathem, fourth wrangler 1894 and Isaac Newton Student in Astronomy, has been elected to a fellowship at St. John's College; and Mr. W. E. Philip, third wrangler in the same year, to a fellowship at Clare College. Mr. W. E. Johnson, of King's College, has been appointed to the University Lectureship in Psychology, vacated by Mr. G. F. Stout, editor of *Mind*.

A COMMITTEE has been appointed to consider the mode in which the grants in aid to science and art schools are distributed, and to report if it is desirable to make any alteration therein. The members consist of the Vice-President of the Committee of Council on Education (Chairman); Mrs. Sidgwick, Sir John F. D. Donnelly, K.C.B., Secretary of the Science and Art Department; Sir H. Roscoe, F.R.S., Mr. G. L. Ryder, H.M. Treasury; Prof. R. C. Jebb, M.P., Mr. W. Armstrong, Director of the National Gallery, Dublin; Captain W. de W. Abney, C.B., F.R.S., Science and Art Department (Secretary).

IT is announced in *Science* that the Chicago Institute of Education has appointed a committee of sixty to develop some feasible plan for carrying on systematic outdoor, or field work, in connection with nature study. The committee held its first meeting on September 19, and a permanent organisation was effected by the election of Mr. Wilbur S. Jackman as President, and Mrs. M. L. T. Baker as Secretary, and the appointment of a number of sub-committees. One of the first works of the committee will be the preparation of maps of the environs of Chicago, which will assist the pupils and teachers of the public schools in a systematic study of the country lying within a convenient radius of the city.

THE sum of £25,000 has now been subscribed for an engineering laboratory at Glasgow University (says *Engineering*), and the same tact and energy which have been displayed in finding the money, will result in an early realisation of the aim of the promoters. The sum of £12,500 was voted out of the Bellahouston Trust Estate, and the remainder has been readily subscribed by engineers and others in the district. Meanwhile a temporary laboratory is to be equipped, two large rooms having been set apart in the main building. This, however, will not even delay the arrangements for the new laboratory. A gas engine of ten horse-power is being presented to the University by the Committee of the Murdock Memorial Fund, and this will commemorate the association of the founder of gas-lighting with James Watt. The testing plant will include a ten-ton machine, with tension, compression, shearing, and bending tackle and an autographic stress-strain recorder, while a melting furnace will be constructed for making alloys.

ABUNDANT evidence of the continued increase in the number of well equipped and properly staffed technical schools throughout the country is afforded by the current number of the *Record of Technical and Secondary Education*, which is published quarterly under the auspices of the National Association for the Promotion of Technical and Secondary Education. A detailed review of the work accomplished in thirteen county boroughs is given; and selected as these are from all parts of the country, they afford an excellent means of judging of the general advance which has taken place since the passing of the Technical Instruction Act of 1890. The photographs of the various departments of the Battersea Polytechnic, and the Victoria Institute, Worcester, show that the plan upon which these new places of instruction are furnished leaves very little to be desired. The editorial notes, with which the publication opens, emphasise the occurrences of special educational interest during the preceding three months, and, together with the article on intermediate education in Wales, they show that the Association has reason to be satisfied with the results of its efforts to improve the knowledge of the workers of this country. Reference is made in the *Record* to the Return recently presented to Parliament, showing that the total income of evening continuation schools in this country amounts to £189,130 3*s*. 1*d*., made up as follows:—Grants by the Education Department, £81,362 3*s*. 4*d*.; grants by the Science and Art Department, £1410 12*s*. 11*d*.; grants by County Councils, £16,440 11*s*. 2*d*.; School Board rates, £58,516 12*s*.; voluntary contributions, £7432 7*s*. 8*d*.; school fees and books, £22,303; endowment, £515 18*s*.; other sources, £1149 14*s*. 4*d*.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, October 30.—Captain Abney, President, in the chair.—Special general meeting.—The Secretary having read a summary of the replies sent by members to a circular which had been addressed to them during the last session, a series of resolutions drawn up by the Council, bearing on the points raised by this circular, were adopted. The chief of these resolutions were to the following effect: (1) That the subscription to the Society be raised to £2 2*s*. (2) That present life-members be invited to voluntarily subscribe £1 1*s*. annually to the funds of the Society, or to compound for this annual contribution. (3) That a guarantee fund be instituted. (4) That in future members of the Society be styled Fellows of the Physical Society of London. In the course of the discussion on these resolutions the President, Secretary, and Treasurer gave an account of the financial position of the Society, and explained that at present each member receives from the Society, in the shape of Proceedings and Abstracts, printed matter which costs the Society more than the amount of the annual subscription. The ordinary science meeting was then held.—A letter was read from Lord Kelvin thanking the Society for the address which the President, on their behalf, had recently presented to him.—Prof. W. Stroud read a paper, by himself and Mr. J. B. Henderson, on a satisfactory method of measuring electrolytic conductivity by means of continuous currents. The method consists in placing a balancing electrolytic cell in the arm of the Wheatstone's Bridge adjacent to the arm containing the chief electrolytic cell, so that the electromotive force of polarisation in the two cells neutralise each other's effect on the galvanometer. The authors find that if the resistance of the arms of the bridge are high (20,000 ohms), and if an E.M.F. of about 30 volts is used in the battery circuit, then the resistance of a solution (of potassium chlorate in their experiments) can be determined to within about one part in two thousand. With a D'Arsonval galvanometer the balancing cell is so efficacious that it is impossible to tell that it is not a metallic resistance that is being measured. Prof. Perry asked if the authors had tested whether the difference in resistance of the two cells was proportional to the difference in length of the liquid columns. Mr. Appleyard said he had found that the resistance of an electrolyte appeared to vary, because in the ordinary arrangement the cell was short circuited through the arms of the bridge. He suggested as a remedy the making and breaking of the circuit by a special key so arranged that, except when taking a reading, the cell is on open circuit. Mr. Blakesley asked if the authors had tried the method in which the resistances are adjusted till, when the battery circuit is broken, there is no immediate change in the galvanometer deflection. It is possible by this method to measure a resistance of between 6000 and 10,000 ohms to within 0·1 per cent. Prof. Ayrton said the method referred to by Mr. Blakesley was the ordinary "false zero" method. In using this method you were working to a continuously altering zero; in Prof. Stroud's method, however, the zero was constant. Mr. Appleyard said he had found the "false zero" method troublesome to use. Prof. Stroud, in reply, said they had not tested the proportionality between the resistance and length, and they had not tried the "false zero" method.—Mr. Appleyard then exhibited a number

of different forms of electrical Trevelyan rockers. The most interesting one consisted of two rods of carbon fixed to a wooden sounding-board, with a third carbon rod lying across the other two, so as to form a microphone. A fairly strong current is passed throught his microphone and through two electromagnets, which act on the prongs of a tuning-fork fixed to the sounding-board. The tuning-fork acts on the microphone, which, by making and breaking the current, keeps the fork in vibration. A cylinder of carbon forming the "knife edge" of a small pendulum, supported on two horizontal carbon rods, kept the pendulum in violent oscillation as long as a current passed from one of the horizontal rods,, through the movable cylinder and out through the other horizontal rod.

PARIS.

Academy of Sciences, October 26.—M. A. Cornu in the chair.—The President announced to the Academy the loss it had sustained by the death of M. Félix Tisserand, Member of the Astronomical Section, and gave a short account of his services to science.—Researches on arabinose, by MM. Berthelot and G. André. The study of the action upon arabinose of water, hydrochloric acid, and phosphoric acid under varying pressures. A continuation of the work already published on glucose, estimations of carbon dioxide, carbon monoxide, formic acid, humic acid, and furfurol being carried out.—Explanation of a note entitled "Cryoscopy of precision," by M. F. M. Raoult. A verbal correction of a previous note.—Observations of the Brooks comet (1889 V.) made at the Observatory of Rio de Janeiro, by M. L. Cruls.—On some linear partial differential equations arising from the theory of surfaces, by M. P. Craig.—On the singularities of the equations of dynamics, by M. Paul Painlevé.—On the distributions of strains in metals subjected to stresses, by M. L. Hartmann. From the hypothesis here developed it is concluded that any solid possessing an elastic limit is necessarily non-isotropic.—On the property of discharging electrified bodies produced in gases by incandescent bodies and by electric sparks, by M. E. Branly. Some remarks on a communication by M. Villari.—On the protection afforded by the lightning conductor at the tower of St. Jacques, by MM. C. Mildé and E. Grenet.—On the periodic maxima of spectra, by M. Aymonnet.—Vapour pressure of a substance compressed by a gas which it dissolves; vapour pressure of a solution in general, by M. A. Ponsot. By considering such a mixture in osmotic equilibrium, a general expression is obtained, which includes the case where the gas is insoluble in the liquid, and the case of aqueous saline solutions.—Hexamethylene-amine and its nitroso-derivatives, by M. Marcel Delépine. Experiments on the heats of combustion and formation of hexamethyleneamine, its nitrate, and two nitroso derivatives.—On the luciferase of animals and vegetables, by M. R. Dubois. The word "luciferase" is applied to the active agent in the production of light in animals and vegetables. The light does not appear to be the result of a combustion or slow oxidation, although the absorption of oxygen is necessary.—Remarks on the digestive organs and mode of nutrition of *Dermochelys coriacea*, by M. L. Vaillant. The digestive organs of this turtle are much more complex than those in allied species, and lead to the conclusion that digestion is carried out somewhat slowly, probably on vegetable substances.—On the discovery of a bed containing vegetable impressions in the old volcanic débris in the island of Phira (Santorin), by M. A. Lacroix. This fossiliferous layer is small, being but a few decimetres thick, and having an area of some square metres, but the imprints are remarkably well preserved. Amongst the plants identified are *Phænix dactylifera*, *Chamærops humilis*, *Pistacia lentiscus*, and *Olea europea*.

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 5.

CHEMICAL SOCIETY, at 8.—The Constitution of Nitrogen Iodide: Dr. F. D. Chattaway.—Note on the Solution and Diffusion of certain Metals in Mercury: Prof Roberts-Austen, C.B., F.R.S.—Compounds of Metallic Hydroxides with Iodine: J. Rettie.—The Economical Preparation of Hydroxylamine Sulphate: The Reduction of Nitrosulphates; and Amidosulphonic Acid: Dr. E. Divers, F.R.S., and Dr. T. Haga.—The Molecular Conductivity of Amidosulphonic Acid: Joji Sakurai.—Physiological Action of Amidosulphonic Acid: Dr. Oscar Loew.—Imidosulphonates Part II.: Dr. E. Divers, F.R.S., and Dr. T. Haga.—How Mercurous and Mercuric Salts change into each other: Seihachi Hada.—The Effect of Heat on Aqueous Solutions of Chrome Alum: Margaret D. Dougal.—The Saponification of Ethylic Dicarboxyl Glutaconate: Dr. H. W. Bolam.—The Periodic Law: R. M. Deeley.—The Colouring Matters occurring in British Plants: A. G. Perkin.—Carbohydrates of Cereal Straws: C. F. Cross, E. J. Bevan, and Claude Smith.

LINNEAN SOCIETY, at 8.—Mediterranean Bryozoa: A. W. Waters.—On some New Species of Crassula from South Africa: Dr. S. Schönland.—Holothurians of New Zealand: A. H. Dendy.

INSTITUTION OF MECHANICAL ENGINEERS, at 7.30.—Breakdowns of Stationary Steam-Engines: Michael Longridge.

FRIDAY, NOVEMBER 6.

GEOLOGISTS' ASSOCIATION, at 8.—Conversazione and Exhibition of Specimens.

TUESDAY, NOVEMBER 10.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Opening Address: The President.—The Jackson-Harmsworth Expedition and the Story of the Last Year's Work: Arthur Montefiore Brice

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Tower Bridge: Superstructure: G. Cruttwell.—The Machinery of the Tower Bridge: Sam. G. Homfray.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.—A New Form of Apparatus for Measuring the Light reflected from Prints: Chapman Jones.—A Theory of the Röntgen Phenomena: Charles E. Benham.

ANTHROPOLOGICAL INSTITUTE, at 8.30.

THURSDAY, NOVEMBER 12.

MATHEMATICAL SOCIETY, at 8.—The Combinatory Analysis: President's Address.—An Essay on the Geometrical Calculus, Part I.: Herr Lasker.—Symbolic Logic: H. MacColl.—On a General Integral with some Physical Applications: G. J. Hurst.—On Ratio: Prof. Hill, F.R.S.—On the Geometrical Construction of Models of Cubic Surfaces: W. H. Blythe.—Theory of Vortex Rings: H. S. Carslaw.—Differentiation of Spherical Harmonics: E. G. Gallop.—On the Application of Jacobi's Dynamical Method to the General Problem of Three Bodies: On certain Properties of the Mean Motions and the Secular Accelerations of the Principal Arguments used in the Lunar Theory: Prof. E. W. Brown.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Telephone Trunk Lines: John Gavey.

SOUTH LONDON ENTOMOLOGICAL AND NATURAL HISTORY SOCIETY, at 8.—Notes and Observations on Acidalia marginipunctata and the Early Stages of the Second Brood of Polyommatus argiolus: R. Adkin.

FRIDAY, NOVEMBER 13.

PHYSICAL SOCIETY, at 5.—On Röntgen Rays: Prof Threlfall and Mr. Pollock.—The Absorption of Electric Waves along Wires by a Terminal Bridge: Dr. Barton and Mr. Bryan.

ROYAL ASTRONOMICAL SOCIETY, at 8.

GALOISIAN ALGEBRA.

Lehrbuch der Algebra. Von Heinrich Weber. Erster Band. Pp. xvi + 654. (Braunschweig: Vieweg und Sohn, 1895.)

A "Treatise on Algebra" is rarely found to fulfil the promise of its title. It is too often a mere collection of problems and examples, thrown together without much regard to order or method; such theory as the book contains is often imperfect, and occasionally even incorrect; and no attempt is made to suggest the idea of an ordered system of algebra, which proceeds along natural lines of development.

Prof. Weber's treatise is a work of an entirely different stamp. It is designed upon a perfectly definite, well-considered plan; its foundations are laid with the utmost care and precision; and the reader is carried on from stage to stage until he is abreast of some of the most interesting, as well as the most recent, of mathematical discoveries. The work may be described, in general terms, as a treatise on ordinary algebra, with special reference to its arithmetical applications; with the addition, subsidiary to the main subject, but very important in itself, of the theory of groups. But in order to give anything like an adequate idea of the author's scope and method, it will be necessary to analyse the different parts of his book in some detail.

The introduction is entirely arithmetical; at the same time it is an indispensable prelude to all that is to follow. It contains the elements of the theory of multiplicities, a rigorous theory of rational and irrational numbers, and a proof of the continuity of real numerical magnitude. The demonstrations are mostly inspired by Dedekind; but it is shown that Cantor's procedure leads to equivalent results. It is to be specially observed that the definitions of rational fractions, ratios, irrational, negative, and complex numbers are entirely independent of any hypothesis about the existence of divisible concrete quantities; and similarly with regard to the statements and proofs of the various propositions. Perhaps in the whole range of mathematics no more abstract reasoning can be found than that by which the continuity of numerical magnitude has been established; and it is very instructive to compare the vague, illusive glimmering of the truth afforded by "intuition" with the precise and logical *Begriff* which has been developed by the persevering effort of mathematical speculation. This is one of the cases where

> "obstinate questionings
> Of sense and outward things"

have justified their stubbornness by leading to discoveries of the highest importance. Arithmetic, and consequently the whole of analysis, has now been absolutely and finally freed from all necessity of appealing to theories or assumptions foreign to its own nature; and the effect of this liberation is already showing itself in many different ways. Thus, for example, in the first book of Prof. Weber's work will be found (pp. 101–126) a strictly arithmetical proof of the fundamental proposition that every algebraical equation in one variable with numerical coefficients has at least one real or complex numerical root. It is true that the proof is accompanied by a geometrical figure, but this is merely for the sake of convenience, and does not affect the real nature of the demonstration. The same thing applies to the proof (pp. 132–6) that the roots of an equation are continuous functions of its coefficients.

The first Book is to a great extent preparatory. It treats, in order, of rational functions of one or more variables, determinants, the existence of roots of algebraic equations, symmetric functions, invariants and covariants, and Tschirnhausen's transformation. The portions most worthy of remark are the proof of the existence of roots as numerical quantities, already alluded to, and the chapter on the Tschirnhausen transformation, which gives a very clear account of Hermite's modified form of the process, by means of which the coefficients of the transformed equation are expressible as simultaneous invariants of the original quantic $f(z)$ and a certain auxiliary quantic $T(z)$. The method is applied to the reduction of the general quintic to the normal forms which are associated with the names of Bring (or Jerrard) and Brioschi.

Book II. deals with the roots of algebraical equations, and comprises six chapters. Of these the first discusses the reality of the roots. The solution of quadratic, cubic, and biquadratic equations is followed by the proof of an important property of the Bezoutiant, namely, that if, by a real linear transformation, the Bezoutiant of $f(z)$ is expressed as a sum of π positive and ν negative squares which cannot be reduced to a smaller number, then $\pi + \nu + 1$ is the number of distinct roots of $f(z)=0$, and of these $\pi - \nu + 1$ are real, and the rest imaginary. (It is understood, of course, that all the coefficients of $f(z)$ are real.) This leads to a digression on Sylvester's Law of Inertia of quadratic forms; after which an application of the theorem about the Bezoutiant is made to the general cubic and biquadratic, and to two special quintic equations.

The Law of Inertia itself is proved in Book I. (p. 183–4): it may perhaps be remarked that on p. 184, line 17, the phrase, "aus diesen μ Gleichungen" is not very clear. What is really meant is the system of μ linear equations, by means of which (*ex hypothesi*) $Z_1, Z_2 \ldots Z_\mu$ are expressible in terms of $Y_1, Y_2 \ldots Y_\nu, Z^1_1, Z^1_2 \ldots Z^1_{\mu 1}$. The supplementary articles on the law of inertia (pp. 255–265) explain how the characteristic numbers π, ν for a given quadratic form may be deduced from the coefficients of the form.

Chapter viii., which next follows, contains an account of Sturm's Theorem which is very fresh and interesting, and includes Hermite's determinants, which may be used instead of the Sturmian functions proper. After this comes a sketch of Kronecker's remarkable theory of characteristics, and an application of it to Gauss's first proof of the existence of roots of equations.

Chapters ix. and x. treat of the separation and approximate calculation of roots. On the whole they follow the traditional lines; and we confess that we did not find them so interesting as the rest of the work. From the author's own point of view, they are, in a sense, superfluous; and, in fact, no use is made of them subsequently. Then from the practical point of view it is hardly satis-

factory to fill up three pages with an account of Daniel Bernoulli's method of approximation, and omit all mention of Horner's algorithm. Still these chapters are redeemed from commonplace by a very elementary proof of Newton's Rule (first demonstrated by Sylvester), a geometrical excursus, after Klein, and some very curious theorems of Laguerre's relating to equations with no imaginary roots.

Chapter xi. discusses continued fractions, arithmetical equivalence, and the theory of the reduction of quadratic irrational numbers. A quadratic irrational $\{a, b, c\}$ is defined to mean

$$\{a, b, c\} = \omega = \frac{\sqrt{D} + b}{2c} = \frac{2a}{\sqrt{D} - b}$$

where

$$D = b^2 + 4ac,$$

and a, b, c are ordinary integers. Thus ω is a definite root of the equation

$$c\omega^2 = a + b\omega :$$

so that the author makes two alterations in the traditional notation of Gauss and Dirichlet. One of these, the substitution of b for $2b$, needs no justification, and has, indeed, become almost inevitable; the reason for the change of sign in c is less obvious, especially as on p. 390 the typical quadratic equation is written

$$A + B\Omega + C\Omega^2 = 0$$

with

$$B^2 - 4AC = D.$$

It is true that, in consequence of this additional modification, there is a trifling gain of typographical elegance; but this seems to be outweighed by other disadvantages.

This chapter concludes with the approximate calculation of roots by means of continued fractions, a brief discussion of rational roots, and a very meagre treatment of what is really a fundamental problem, namely the resolution of a polynomial with integral coefficients into its irreducible factors. It is true that a method is given which is theoretically sufficient, but this is quite useless in practice; while, on the other hand, the purely tentative method illustrated by an example can only be made conclusive by special artifices. Some account ought, we think, to have been given of Kronecker's algorithm (Crelle, vol. 92), which, although tedious, is really practicable, and has the advantage of giving a definite answer after a finite number of trials which may be estimated beforehand.

Chapter xii. contains the elementary theory of the roots of unity, primitive roots to a modulus, indices, quadratic residues, and the law of quadratic reciprocity: the proof of this last is the trigonometrical one of Eisenstein.

We now come to Book III., on "Algebraical Quantities," and here the essential and characteristic part of the work may be said to begin. The key-note is struck at the commencement of chapter xiii. by the definition of a numerical corpus (*Zahlkörper*). The notion of a corpus, which is of the most fundamental character, is due to Dedekind, and is as follows. Let us take a finite or infinite system of elements α, β, γ, &c., concerning which nothing is assumed except that they can enter into rational combination according to the rules of ordinary algebra; then the totality of all rational functions of α, β, γ, &c., except those which involve division by zero, constitutes a corpus, denoted by

$$\Omega(\alpha, \beta, \gamma \ldots).$$

The simplest corpus is that of all rational numbers. This is contained in every other corpus; for if ω be any element of the corpus, then by definition the corpus contains ω/ω, that is, unity; and from this all other rational numbers may be derived by rational operations only.

If the elements of a corpus are all numbers, it is called a numerical corpus; but the elements may be independent variables, or even variables subject to algebraical conditions.

If $\Omega(\alpha, \beta, \gamma \ldots)$ is any corpus, and x any quantity not contained in it, the corpus $\Omega(x, \alpha, \beta, \gamma \ldots)$ is said to be derived from $\Omega(\alpha, \beta, \gamma \ldots)$ by the adjunction of x.

If z is an undetermined variable, the polynomial

$$f(z) = a_0 z^m + a_1 z^{m-1} + \ldots + a_m$$

is said to be a function in Ω when all the coefficients a_0, $a_1, \ldots a_m$ belong to Ω.

When Ω is given, we may, if we like, regard all the quantities belonging to it as rational: for this reason Kronecker calls a corpus a domain of rationality.

A function in Ω is reducible (in Ω) if it can be resolved into the product of two functions in Ω. A function which is irreducible in Ω may be reducible in a corpus derived from Ω by adjunction.

Let $f(z)$ be an irreducible function in Ω, of the nth degree in z; then the equation

$$f(z) = 0$$

is assumed to have n conjugate roots $z_1, z_2 \ldots z_n$. If Ω is a numerical corpus, the roots have actual numerical values; but this is really immaterial so far as the general algebraic theory of the corpus is concerned.

By the separate adjunction of the roots, we obtain the conjugate corpora $\Omega(z_1)$, $\Omega(z_2) \ldots \Omega(z_n)$, each of which is called an algebraical corpus of the nth degree. These conjugate corpora are not necessarily all different; they may, in fact, be all identical, and the corpus is then called a Galoisian or normal corpus. In this case all the roots z_i are expressible as rational functions of any one of them, and this leads to the definition of a normal (or Galoisian) equation.

In the chapter we are now considering, the author proves the important theorem that the simultaneous adjunction of several algebraic quantities is equivalent to the adjunction of one only, provided that it be appropriately chosen; develops the distinction between primitive and imprimitive corpora; defines the Galoisian resolvent of an equation; and shows that the corpus $\Omega(z_1, z_2, \ldots z_n)$, derived from n conjugate corpora, is normal. This last proposition is the master-key to the whole Galoisian theory. After this we have a discussion of the substitutions of a normal corpus; it is important to observe that their number is equal to its degree. Then comes a brief digression on the elements of the theory of permutation-groups; and this leads to the very important conclusion that the group of μ substitutions of a normal corpus which contains n conjugate algebraical corpora is isomorphic with a certain group of permutations of n things. This may be regarded as a group of permutations of the n conjugate roots, and

is then called the Galoisian group of the corresponding equation.

The problem of the algebraical solution of an equation ultimately depends upon the nature of its Galoisian group, or, which comes to the same thing, of its Galoisian resolvent. The degree of this resolvent is equal to μ, the degree of the Galoisian group; if this is equal to $n!$ (n being the degree of the proposed equation), the equation is said to have no *Affect*. So long as we confine ourselves to the corpus $\Omega(a_0, a_1, \ldots a_{n-1})$, the general equation

$$a_0 z^n + a_1 z^{n-1} + \ldots + a_{n-1} = 0$$

has no *Affect*. But, by the adjunction of an appropriate algebraical quantity, the Galoisian resolvent may become reducible, and then any one of its irreducible factors is a Galoisian resolvent in the new domain of rationality. The process may admit of repetition, and we may say that the problem ultimately consists in finding algebraical quantities of the simplest possible kind, so that by their successive adjunction we may obtain a series of resolvents of lower and lower degree. No such reduction can be effected by the adjunction of irrationalities which are not contained in the normal corpus $\Omega(z_1, z_2, \ldots z_n)$ which is derived from the original equation. After the proof of this very important result (p. 516), the chapter concludes with a further discussion of imprimitive groups, with special reference to the Galoisian resolvent.

Chapter xv., on cyclical equations, contains applications of the foregoing theory, and should be read concurrently with chapter xiv. by those to whom Galois's theory is new. First of all, the general cubic and biquadratic are solved by a direct application of group-theory; and we are then introduced to the theory of Abelian and cyclic equations. An Abelian equation is a normal equation whose Galoisian group is commutative. It is not necessarily irreducible; on the other hand, an irreducible equation with a commutative group is necessarily Abelian (p. 535).

A cyclical equation is one whose group consists of a single cyclical substitution and its powers; in other words, when its roots may be arranged in such an order that all cyclical functions of them are rational. The solution of any Abelian equation may always be reduced to that of a system of cyclic equations (§ 163). The chapter concludes with the solution of cyclic equations by means of Lagrange's resolvent.

Chapter xvi., on cyclotomy, gives the theory of Gauss's periods, of the auxiliary functions which Jacobi denotes by $\psi_\lambda(a)$, of the solution of cyclotomic equations by their means, and of Gauss's sums. It concludes with applications to complex numbers of the forms $x + yi$, $x + y\rho$, ρ being a cube root of unity. It may be observed that the properties of the numbers $\psi_\lambda(a)$ are very fully treated in Jacobi's lectures on the theory of numbers. These are not included in his collected works; but MS. copies of Rosenhain's redaction of them may be picked up occasionally.

Chapter xvii. contains a series of remarkable propositions, which are proved with comparative ease by means of the foregoing theory. First of all it is shown that if P, the group of an equation, is reduced by the adjunction of the roots of an Abelian equation, P has a normal divisor Q, the index of which is a prime; and, conversely, if P has a normal divisor of this kind, P may be reduced in the manner stated. (By a normal divisor of P is meant a self-conjugate sub-group, or, as Klein calls it, an "ausgezeichnete Untergruppe.")

We then pass on to the theory of metacyclic equations. A metacyclic equation is defined as one whose complete solution may be made to depend on that of a series of cyclic equations. It is shown (p. 598) that the necessary and sufficient condition to be satisfied by a metacyclic equation is that there should exist a series of groups

$$\Gamma, \Gamma_1, \Gamma_2, \ldots 1$$

(of which the first is the Galoisian group of the equation) such that each group is a normal divisor, with prime index, of the group immediately before it in the series.

It is subsequently proved (§ 180) that the group of a metacyclic equation of prime degree is linear; that is to say, if its roots are

$$x_1, x_2, \ldots x_r, \ldots x_p$$

the group consists of the $p(p-1)$ permutations of the suffixes defined by

$$t' \equiv at + b \pmod{p},$$

where a may have any of the values 1, 2, ... $(p-1)$, and b any of the values 0, 1, 2 ... $(p-1)$.

Conversely every irreducible equation of prime degree whose group is linear, is metacyclic (p. 615).

A function of the roots x_r which is unaltered by the permutations of the linear group, and by these only, is called a metacyclic function. Every metacyclic function is a root of a rational equation $F(y)=0$ of degree $(n-2)!$ and the function y may be so chosen that this equation has no multiple roots. Assuming that y has been so chosen, the necessary and sufficient condition that a given equation $f(x)=0$ may be soluble by radicals is that the resolvent $F(y)=0$ has a rational root (p. 620). This very beautiful proposition is the complete answer to the question first definitely put by Abel, namely: What algebraical equations are soluble by radicals?

At the end of this chapter will be found a very interesting application to metacyclic quintics. Among other things it is shown that if λ and μ are any two rational quantities, and

$$\alpha = \frac{5^5\mu^4\lambda}{(\lambda-1)^4(\lambda^2+6\lambda+25)^5}, \qquad \beta = \frac{5^5\mu^5}{(\lambda-1)^4(\lambda^2+6\lambda+25)^5}$$

the quintic

$$x^5 + \alpha x + \beta = 0$$

may be solved by radicals.

One problem still remains: the actual construction of all possible metacyclic equations. This is considered in chapter xviii., the last in vol. I. The complete solution was announced by Kronecker, in his usual oracular way, in the Berlin *Monatsberichte* for 1853 and 1856. Prof. Weber here supplies us with a demonstration, which reproduces in an improved and simplified form his own Marburg memoir of 1892. It is based upon the properties of Lagrange's resolvent; and although it is impossible to analyse it in detail, the final result may be stated.

"Every root ξ of a metacyclic equation of prime degree n may be expressed in the form

$$\xi = A + \sum_{s=0}^{s=n-2} K_s \tau_s^{r_{n-2}-r_{n-3}} \tau_{s+1}^{r_{n-3}} \ldots \tau_{s+n-2}^{r_0}$$

where A is a rational quantity, $\tau_s = \sqrt[n]{k_s}$, K a rational

function of k_r the form of which is the same for all values of s. The quantities k_r are the roots, different from each other, and from zero, of a cyclical equation of degree $(n-1)$. The exponents $r_0, r_1, \ldots r_{n-2}$ are the least positive residues of $1, g, g^2, \ldots g^{n-2}$ to the modulus n; g being a primitive root of n. The n values of ξ, obtained from this formula by giving to the radicals r_s their different values, are the roots of one and the same rational equation.

"Moreover every quantity ξ of this form is the root of an equation of the nth degree rational in the corpus K, whose elements are the coefficients of the equation satisfied by $k_0, k_1 \ldots k_{n-2}$. This equation in ξ is irreducible, except in the special case when one of its roots is rational." (With regard to the last clause, see the Corrigenda at the end of vol. II.) If the corpus K is real, the quantities k are either all real or all imaginary (see p. 551); in the first case one root ξ is real and the rest imaginary, in the second case all the roots ξ are real.

The last five pages of this volume contain the explicit determination of all metacyclic quintic equations.

An account of vol. II., and a general review of the whole work, is reserved for another article.

G. B. M.

OUR BOOK SHELF.

Hours with Nature. By Rambramha Sanyal, C.M.Z.S. Pp. 168. (Calcutta: Lahiri, 1896.)

As a first attempt on the part of a native Indian naturalist to familiarise his countrymen with some of the leading facts in nature, and to cultivate in them the faculty of observation, this little volume is clearly entitled to a welcome at our hands. To criticise the English would obviously be unfair, seeing that the author is writing in a foreign tongue; and, indeed, if this be borne in mind, his work is worthy of all praise, so far as this point is concerned.

Babu Sanyal, as stated on the title-page, is Superintendent of the Calcutta Zoological Gardens, where he has many opportunities of observing the habits of animals but little known in Europe. One communication from his pen—on the habits of Bennett's Mungoose (*Cynogale bennetti*)—has already appeared in the London Zoological Society's *Proceedings*; and it is a matter for regret that other observations on the habits of animals under his charge have not found a place in this volume. As the book is essentially a medley, to give an account of its contents is somewhat difficult. It commences with the description of an excursion in Bengal, in the course of which we are introduced to the Gangetic dolphin, kingfisher, and various other birds, squirrels, and the famous Botanical Garden at Calcutta. Chapter ii. gives us a history of the former superintendents of that institution, mainly compiled from the official handbook. In the third chapter the author takes the misapplication of the term "mole" to the Indian musk-shrew as the text for a sermon on moles and shrews; while in the next section we pass to such a widely different subject as an aquarium and its denizens. Of the other chapters, we can only mention that the sixth describes the tour of a party of Bengalis round the Indian Museum, Calcutta, while the ninth relates to Indian snakes; perhaps the best in the book, the author emphasising the "rib-walking" character of these animals. If the book reaches a second edition, we would, however, advise him to study Mr. Boulenger's works, when he would probably amend his classification of reptiles, and point out some means of distinguishing between snakes and limbless lizards.

It may be hoped that this little work may succeed in its object of awakening a love of nature, and exciting observation among our Bengali fellow-subjects.

R. L.

Elements of Astronomy. By Sir Robert Ball, LL.D., F.R.S. New edition, thoroughly revised. Pp. 469. (London: Longmans, Green, and Co., 1896.)

THIS edition has been subjected by the author to a thorough revision, special attention having been paid to the last chapter, which deals exclusively with astronomical constants. These latter will be found most interesting and valuable to all classes of astronomical students, for besides being presented with the facts in each case, references as to the source of information are always added. Little need be said about the other chapters, as the revision seems to have been very thorough, although occasional omissions have been found. We may, however, mention that the illustration on page 44 seems to be rather out of date, and might have been changed for one more modern. In paragraphs relating to stellar classification, perhaps it would have been better to refer to a more recent classification, in which we have every reason to believe that stars do not simply decrease in temperature, but both increase and decrease. Putting aside these two minor details, the book will prove an excellent text-book for those wishing to acquire a knowledge of the more important problems relating to astronomy. The admirable index attached will be found most complete.

Practical Work in Physics. By W. G. Woollcombe, M.A., B.Sc. Part iii. Light and Sound. Pp. x + 94. (Oxford: Clarendon Press, 1896.)

THIS is the third part of a course of practical physics, the two previous ones dealing with heat and general physics. A fourth part, on electricity and magnetism, will complete the work. The optical experiments in the present volume illustrate photometry, reflection at plane and at spherical surfaces, refraction at plane surfaces, and through lenses. The experiments in sound demonstrate the laws of transverse vibrations of wires, velocity of sound through gases and through solids, and interference of sound-waves. Only inexpensive apparatus is needed in order to carry out the experiments described, and the instructions, both as to construction of apparatus and performance with it, are clear and practicable. Experiments in sound depend upon the physiological perception of tone, and some students are unable to accurately perform them. The number of students with no "ear for music" (musicians will, perhaps, pardon the designation of the twanging of a monochord as music) is, however, very small. Mr. Woollcombe says that only five per cent. of his students have so little musical sense that the experiments in sound he describes cannot be satisfactorily carried out by them; and his experience is about the same as that of most teachers and demonstrators of physics.

Peasblossom. The Story of a Pet Plant. By Caroline Pridham. Pp. 180. (London: John Heywood.)

TAKEN altogether, this book is very attractively written. The descriptions are couched in the simplest words, and no botanical terms are used without full explanation. Observation is the basis of the text, and the development of a plant is traced from germination upwards, all the parts and all the stages being considered. The book will interest young readers, and will encourage them to study the life-history of common plants; the knowledge they will thus gain from text and nature will be worth having.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Austro-Hungarian Map of Franz Josef Land.

In common with all who take an interest in Arctic research, I was very much surprised to learn, on the return of the *Windward*, last year, that the Jackson-Harmsworth polar expedition had detected, what seemed to them, extraordinary inaccuracies in Payer's map of Franz Josef Land. Finding, however, that Mr. Jackson's sledge journeys had only been directed along the very outskirts of the region laid down by Lieut. Payer, I came to the conclusion that the discrepancies pointed out were no greater than might be expected in a part of the map, where the Austrian explorer had obviously meant rather to indicate the presence of some geographical feature, than to give its exact position. I also hoped that Mr. Jackson's persevering endeavours would eventually lead him to some point where he could effect a satisfactory juncture of his own survey with that of his predecessor.

When, however, on August 13 last, I had the great pleasure of meeting Dr. Nansen at Vardö, a few hours after he had landed from the *Windward*, I was absolutely astounded when he informed me, with evident distress, that the northern part of the well-known map of Austria Sound was utterly wrong. Indeed the circumstantial and graphic telegrams, which at that moment were being flashed round the whole globe, told how Dr. Nansen and Lieut. Johansen, on their unparalleled return journey, had failed to identify a single geographical feature discovered by the intrepid Austrian explorer; how, on the contrary, they had, on August 6, 1895, found three snow-covered islands in 81° 38′ N. lat. and about 63° E. long., and how they afterwards slowly worked their way to their winter quarters in 81° 12′ N. lat. and 56° E. long.; thus, to all appearance, actually crossing Payer's sledge tracks without finding any agreement with his map. The three islands just mentioned would, according to Dr. Nansen's determination, come in the very middle of Lieut. Payer's Dove Glacier. The publication of Dr. Nansen's book can alone enable geographers to decide as to the relative positions that Austria Sound and the three islands of the Norwegian explorers have to occupy on the map.

Respecting the accuracy of the southern part of Lieut. Payer's map, there can be no doubt whatever; for if we turn to the third section of the "Denkschriften der Kaiserlichen Akademie der Wissenschaften," Band xxxv., Vienna, 1878,[1] we shall find from Weyprecht's paper on the astronomical and geodetic results of the Austro-Hungarian Arctic expedition, that the latitudes and longitudes of the *Tegetthoff* in the land ice, and of certain points on the neighbouring coast, notably Cape Tegetthoff and the western extremity of Wilczek Island, have all the precision that could be obtained from a long series of meridian altitudes, and no less than 218 lunar distances,[2] combined with a systematic triangulation. This triangulation was connected with all the neighbouring islands within a distance of some 30 or 40 miles. The satisfactory character of this part of the map was proved by Mr. Leigh Smith, who, during his first voyage to Franz Josef Land, passed close under Cape Tegetthoff and the south-western shore of Wilczek Island, where he saw, but did not visit, the large cairn in which the Austrian explorers placed a number of documents and a minimum thermometer. (See "Denkschriften," *l.c.*, p. 67, where the late Lieut. Weyprecht placed on record directions for opening the cairn without moving the thermometer from its horizontal position, and thus sacrificing the valuable indication it may yet afford.)

Naturally the survey grew less accurate when it came to be extended up Austria Sound; but even there the latitudes, at least, must be very near the truth, as they are founded on numerous meridian altitudes of the sun. Fortunately an observation was secured in 81° 57′ N. lat. within a few miles of the most northern point reached. Hence there is no reason whatever to doubt that Lieut. Payer and his two companions, Midshipman Orel and the seaman Zaninovich, attained the latitude of 82° 5′, as detailed in the document now lying in a bottle on the summit of Cape Fligely. Unfortunately there is not the same certainty with regard to the longitudes, at least in the northern part of the map, as they rest solely on compass azimuths or bearings taken with the theodolite, often observed under very unfavourable conditions. (See Payer's "New Lands within the Arctic Circle," vol. ii. p. 77.) Had circumstances permitted the astronomical determination of a single longitude near the northern limit of the survey, no uncertainty as to the position of even the remoter parts of Austria Sound could have arisen. In conclusion, it may be mentioned that Lieut. Payer has deposited with the Royal Geographical Society all the materials used in the construction of his map; it is quite possible that a careful revision of these papers may remove the remaining uncertainty which, at present, hangs over the position of the northern part of the land which my old comrade explored in the face of so many difficulties.

RALPH COPELAND.

Royal Observatory, Edinburgh, November 6.

[1] This volume is devoted exclusively to the scientific results of the expedition under Payer and Weyprecht.

[2] Near the poles lunar distances define the observer's position much more accurately than in lower latitudes, not only because the degrees of longitude are less, but also on account of the smaller parallax in right ascension. It is therefore earnestly to be desired that explorers on boat or sledge journeys should avail themselves of this invaluable method.

The Inheritance of Specific Characters.

Prof. Meldola (NATURE, October 22, p. 594), referring to the increasing breadth of carapace in growing crabs, suggests as an alternative to selection acting during the present life of the individuals, that "breadth of carapace . . . had a selection value in the phylogeny; now this character appears at a late stage in the ontogeny." Before accepting this interesting suggestion as plausible, one would like to hear, from Prof. Meldola or any one else, of other instances in which a character that has been of selection value "in the past history of the species" does not appear until a late stage in the present individual history. My own knowledge does not extend further than the fact that such characters tend to be inherited at an earlier stage; of their inheritance at a later stage, I know no instances. Were this a universal principle, the selection of broader carapaced individuals must have taken place not very long ago, the conditions can hardly have been very different to now, and, as now, the character must have appeared at a late state in the ontogeny; in short, Prof. Meldola's alternative would only shift the need for an explanation a little distance back. The principle, however, may not be so general in its application as many of us have been led to believe. But, since in zoological speculation an hypothesis should be proved consonant with some known fact, Prof Meldola may fairly be asked to adduce facts in harmony with the idea which he states he has always entertained.

Since your report of the discussion on Neo-Lamarckism in Section D at the British Association meeting will doubtless be regarded as authoritative, may I take this opportunity of correcting the sentence, "Mr. F. A. Bather thought the Ammonites afforded at least some proof of the Neo-Lamarckian doctrine." He may have "thought" so, though I greatly doubt it, but he certainly did not say so. He was using the Ammonites as an example, to ask Prof. Lloyd Morgan how a modification of the senile parent could affect the limits of variation in its offspring, most of which had already been produced; or how modification even of the adult could affect the limits of variation in its offspring, which do not present the character of the assumed modification until they themselves become adult. The point of these questions would be more obvious to your readers, had your report alluded to the thesis that I imagined to constitute Prof. Lloyd Morgan's main contribution to the discussion.

F. A. Bather.

In the first place, I will take the opportunity afforded me by Mr. Bather, of correcting a slip in my letter: it is narrowness of carapace that is being, or has been, selected, and not breadth, as I stated. This, however, in no way affects the suggestion. In the next place, I must part company from Mr. Bather on a point of fundamental principle. I decline to accept, as a canon of scientific method, that a zoological (why particularly "zoological"?) hypothesis put forward in explanation of a body of facts still under investigation, and, possibly, leading us on to new principles, should, in order to become plausible, "be proved consonant with some known fact." I take it that, in making tentative suggestions for the interpretation of results obtained by observation, as in the case under consideration, it is sufficient, if the hypothesis is not opposed by any known fact. I did not lay it down as a dogma that selection *must have acted* in the way

stated. In fact, Prof. Weldon's original interpretation has not yet been, and never may, be disproved, and, for all we know to the contrary, selection may still be acting in the direction indicated by his measurements. Mr. Bather will see, on reference to my letter, that I advanced the idea "for whatever that idea may be worth." It appears necessary to point out that the "facts" are before us in this case; it is a question of interpretation. The difficulty raised by your correspondent is one of his own creation, and not one of mine. Where have I stated, or even suggested, that the appearance of a character which formerly was of selection value, and which now appears in the later stage of individual development, is a "universal principle"? If the suggestion which I made with reference to the interpretation of Prof. Weldon's results is sound in principle, it is obvious that it refers to a (comparatively) recent cessation of selection, and so far Mr. Bather has correctly grasped my meaning. When, however, he lays it down, on his own responsibility, that the conditions then "can hardly have been very different to now," he is laying claim to a knowledge of the past and present conditions of life and to a familiarity with the time necessary to bring about the modification of species, at which I can only stand aside with envy and admiration. If Mr. Bather really must have some "known fact" after this distinct dissociation of myself from his methods, I will refer him to those cases of mimetic butterflies which have no models. There is good reason for believing that certain butterflies which are undoubted mimics, since they depart from their allies in type of pattern, have for some unknown reason survived, while the species which they imitated have, also for unknown reasons, become extinct. The mimics still retain their mimetic pattern and colouring, but the selective process which produced this type can no longer (in the absence of the model) be regarded as in active operation. Nevertheless, the mimetic disguise is retained by virtue of heredity, and appears in the last stage of the ontogeny. Your correspondent will, I hope, pardon any apparent discourtesy if I state that the correspondence on this subject is, so far as I am concerned, now closed. I can assure him that he shall hear more about the results of Prof. Weldon's measurements at no very distant future. R. MELDOLA.

Measurements of Crabs.

MR. CUNNINGHAM, in NATURE of October 29, raises a doubt as to the trustworthiness of the results of my measurements of crabs, on the ground that the specimens of the year 1893 had been longer in spirit than those of 1895.

The value of measurements made on animals preserved in spirit naturally depends on the animal so preserved; and to any one who is acquainted with the rigid nature of the calcareous carapace of *Carcinus mœnas*, it seems difficult to admit the possibility of distortion from such a cause. All specimens that were not quite rigid (a condition due to the animal having moulted just before capture) were rejected as a matter of course.

The fact that a deficiency in one dimension was "compensated" by an excess in the other dimension, so far from suggesting to Mr. Cunningham a suspicion of the specimens having "undergone an artificial change of shape," would, I think, have seemed not only natural, but a feature to be expected, had he realised that every crab during its growth passes through a similar change of shape, in which the relative increase in size of the one dimension (the dentary margin) is accompanied by a corresponding relative diminution in size of the other dimension (frontal breadth). The table appended to the paper in question shows that, while the dentary margin in the youngest crabs measured increased on an average from 414 thousandths of the carapace length to 498 thousandths in the adult, the frontal breadth, on the other hand, diminished in relative size from 813 thousandths in the young to 595 thousandths in the adult; so that a compensatory relation between these two parts of the hard skeleton is a normal phenomenon in these animals.

I would venture to add that observations in recent years, on the variability of both animals and plants, tend to show that species are much more unstable than was once supposed. The changes recorded in these crabs in the space of two years are very minute, but they are persistently in one and the same direction in all the twenty-six stages of growth measured. If such a rate of change exceed what we should have expected, it may be because hitherto we have had no collections of comparative facts on which to base any reasonable expectation. H. THOMPSON.

October 30.

I AM able to offer Mr. Cunningham direct experimental evidence that the hard carapace of a young shore-crab is not sensibly distorted by immersion in spirit for six months.

I have lately had occasion to compare the mean frontal breadth in three samples of young female crabs, gathered from the same locality in Plymouth Sound. The range of size was the same in all the samples. The samples were (1) a large number of individuals, collected in 1892 and 1893, measured after immersion in spirit during a period varying between six months and a year: the mean frontal breadth in these crabs was compared (2) with that of 569 individuals, collected during the summer of 1895, and measured fresh while still wet with seawater; and (3) with that of 595 crabs, gathered also during the summer of 1895, but preserved in spirit for about six months before measurement.

The mean difference between the frontal breadth in the spirit specimens of 1892–3 and that of the fresh specimens of 1895, was 1·47276 of Mr. Thompson's units; the difference between the crabs of 1892–3 and the spirit specimens of 1895 was 1·58992 units. The difference between the two results obtained from crabs of 1895 was therefore only 0·11716 unit—a difference so small, compared with those observed by Mr. Thompson, that it may safely be neglected, even if it be assumed to be due entirely to the spirit, and not to be within the probable error of the determination. As for the distribution of deviations from the mean in the two samples, it would take too much space to compare them in detail here; I hope to do so before very long in connection with another problem, and therefore I will only now say that the "standard deviation" (= error of mean square) of the series of fresh shells was in Mr. Thompson's units 11·7955, that of the spirit specimens being 11·9628 of the same units.

These figures seem to me sufficient to justify Mr. Thompson's conclusion; and it must therefore be held that a change, whether of oscillation or of evolution, is going on at a measurable rate among *Carcinus mœnas* in Plymouth Sound.

The very great importance of this result to all students of animal evolution is evident; for the careful study of cases in which change is actually going on so rapidly that it can be watched and measured in a reasonably short space of time will assuredly be found to give the best, if not the only clue to the process of evolution in general. W. F. R. WELDON.

University College, London, October 31.

The X-Rays produced by a Wimshurst Machine.

IN my two papers of June 4 and June 18 respectively, I proved the existence of non-homogeneity in the X-rays, and gave a simple method of strengthening and maintaining the discharge of these rays from an ordinary focus tube by means of a conductor wrapped round the part of the tube level with and behind the kathode, and separated by a small sparking gap from either an earthed wire or the kathode's external wire loop, or the wire leading from the induction coil to the kathode itself. Since then my attention has been chiefly turned to the most remarkable results which can be attained with a Wimshurst machine, with which this paper is concerned. My Wimshurst has two 15-inch plates, and, not being of the latest type, has the old-fashioned metallic sectors and buttons, instead of the plain varnished glass disc, though I do not imagine that the results will be found materially different with the simpler, and probably better, form.

At first I drove the machine by hand, and hand driving is sufficient for the results mentioned in this paper—a most important fact, seeing that it renders unnecessary any other form of engine than the hand, and brings the copious production of any kind of X-rays within the reach of those who have neither battery nor dynamo—afterwards, for securing greater personal freedom and uniformity of turning force, I drove the Wimshurst by a small motor, an easy and most convenient plan, using a platinum electrode acidulated water resistance by which the rate of rotation is easily governed.

To me, accustomed only to the effects given by a 4½" spark induction coil, the brilliancy of the shadows given by simply connecting my tube's electrodes to the brass knob terminals of the Wimshurst used without condensers was surprising, and the steadiness of the image a most grateful rest to the eyes. The bones seemed more transparent than I had ever seen them, and though at first I thought this might be only the effect of the lessening contrast brought about by increased general illumination, this does not prove to be the case. The two faults to be

found with the Wimshurst used in this way are, first, that after a rest or complete discharge the polarity of the machine is apt to reverse, the cure being either (*a*) to completely discharge again and trust that the desired reversal will take place on re-starting, a very uncertain plan; (*b*) to interchange the wires, probably best by disconnecting them at the tube and turning the tube suitably; or (*c*) by discharging completely and starting the electrical action of the machine by holding in some position, found easily by experiment, a body electrified and whose electrification is of known sign—*e.g.* a glass rod rubbed quickly and lightly on a piece of silk or flannel. The second fault is that in this way of using the Wimshurst, whether the condensers are in circuit or not, after a time the character of the discharge is apt to alter. Beautiful patches and streaks of very bright grass-green make their appearance on the inner surface of the glass; and when one of these has formed, the X-ray discharge becomes weaker, and two or three are altogether fatal to it, even if the machine be in excellent working order. When once a patch is formed, too, it seems to cling obstinately to the place where it develops. It was suggested to me that these patches were invariably associated with bubbles in the glass of the tube, but on touching the tube lightly with a camel's-hair brush dipped in rather dry Indian ink, and thus painting over these green spots whilst they were visible, and afterwards removing the ink spot by spot and examining for bubbles, I found in many cases they were not present, and also that there were many bubbles where no fluorescent spot had been painted. These spots lie in the shortest lines which can be drawn on the glass from the kathode to the anode. They are far more numerous near the kathode, forming near it, and often gradually elongating towards the anode. Blowing gently on the middle part of the tube causes their retreat towards their birthplace, and often extinguishes them altogether. Their forms seem to be those which slightly divergent jets of matter would take if they were thrown out from different points on the sharp edges of the kathode and impinged on the inner surface of the bulb very near the kathode, exciting fluorescence so long as the matter maintained a velocity above a certain limit. If this is so, and the matter is negatively charged, and if the glass surface acts to it as a rough surface does to a stone, perhaps on account of its high electrical resistance, it is easy to see why the patches are small and slowly spread when a higher E.M.F. is used, and how it is that the dissipation of the positive charge which lies on the outside of the bulb leaves these jets of negatively electrified particles more free to take a shorter path to the anode. Thus, if they hit the glass at all, they will do so further and further from the kathode; and this explains why the fluorescent patches travel towards the anode region of the bulb, when the neighbourhood of the kathode is deprived of its positive charge by gently breathing on the glass in this part of the bulb. Similarly it also explains why the patches travel kathode-wards when the middle and anodal region is drained in any way of its positive charge, for then the attraction in the kathodal region is practically strengthened by the destruction of the attraction to other glass parts of the tube. Not only do these jets impinge on the inner side of the glass just by the kathode under ordinary circumstances, when no pains are taken to drain the external positive charge of the tube, but they are partly reflected, and, owing to the attraction of the positive charge, the path of the reflected particles is bent towards the glass surface, and in many cases a fainter patch of longer shape is formed further from the kathode, and I believe a third may be, so that the inner surface of the tube tends to become filled with patches smallest, brightest, nearest together and least elliptical, near the kathode; and becoming progressively larger, fainter, further apart, and longer in proportion the nearer they approach the anode. This has a very important application, for seeing that the formation of the patches is, by experiment, inimical to the creation of the X-rays, anything which tends to their formation must be avoided; and if, as I am convinced, they are due to the sharp edges and small irregularities of the circular kathode, no pains should be spared to give that electrode a perfect polish on the side facing the anode, and to make its edge circular, and not square, as the circular kathode's edges are in my tubes. Another way of partly overcoming this difficulty is to make the tube very wide round the kathode, or, which amounts to the same thing, push the kathode well forward into the globular part of the tube. This last is done in some tubes, I believe, with excellent results. A striking experiment is to arrange a tube and Wimshurst to give the green patches, and then to breathe rather strongly on the kathode half of the tube two or three times if necessary, and watch how the phosphorescent patches fly towards the anode as the external positive charge is dissipated and, at last, just meet behind the anode (which region becomes brightly fluorescent); finally, if the positive charge is sufficiently dissipated, part creeping and part bounding along the glass tube which, in my tube, encloses the anode's wire support, into which support, or the actual back of the anode, they finally yield their negative charge. I think that any one, who will take the trouble to make the very easy experiments here recorded for himself, will feel convinced that this is the true explanation of many of the—so far as I know—widely observed, but unexplained variations in the behaviour of the X-ray tubes, and the last experiment suggests that it would be a good thing to (i.) completely surround the anode stem and the back of the anode itself with some insulator—glass would probably prove best—and if the anode be platinum, to make the anode's edges very blunt and smooth; and it may be well, but of this I cannot feel certain without experiment, to make a small area, large enough to include the point from which the X-rays seem to emanate, rough with, say, platinum black, in order that over this area, to put it in old-fashioned language, the density of the positive electrical charge may be as great as possible.

In these ways, perhaps, the stray negative "jets" may be prevented, and a tube made to emit the X-rays more easily and steadily than any at present used.

It seems natural, from these conclusions, to suppose that pushing both anode and kathode far into the tube so that they are fairly close together, is a very good plan, for it would certainly tend to prevent leakage to the internal surface of the glass. I have heard that very excellent results have been obtained with tubes in which the electrodes are but a very few millimetres apart. The same reasoning would indicate that it would be well to make the kathode convex towards the anode, and fairly small, but not very small; for each tube there will be a special size which will be best.

Whatever the nature of the "jets" may be—and I suppose most will be inclined to believe (with Crookes) that they are particles of the residual air, for there is very little evidence of any scattering of an aluminium kathode, save just round its edge—it is clear that the effect of the external positive charge is to create a higher vacuum in the central portion by drawing the particles to the sides of the tube; and this accounts for the action of a flame on the glass bulb, which is two-fold—for it not only drives off from the sides, and possibly from the electrodes, particles of moisture or occluded gases held by some force other than electrical, but also speedily dissipates the external charge, and thus frees the "electrically bound" molecules, distributing the matter more evenly over the internal space, and thus making the passage of electricity between the electrodes easier. At the same time the phosphorescence, which is produced by their impact on the glass, becomes evenly distributed over the tube, and it is whilst hot that the X_2-rays are emitted (to which wood is transparent, but flesh opaque); and it should be particularly noted that these X_2-rays are in this case emitted when the tube offers less resistance to the electrical discharge than when the X_1-rays (which penetrate flesh, but to which bone is fairly opaque) are being emitted.

Several observers—in particular, Mr. Swinton—have mentioned that under some conditions a tube is capable of emitting rays to which bone is almost as transparent as flesh. These I shall call throughout the rest of this paper X_3, and in the experiment I am about to describe it will be found that it is possible—and, indeed, very easy—to cause a tube to emit either X_2, X_1, or X_3-rays; and not only so, but inasmuch as the change from X_2 through X_1 to X_3 is perfectly continuous, it is simplest to believe they differ, not in kind, but only in some one inherent quality, such as frequency, which varies continuously. I may say, beforehand, that the following experiment seems to me a very important one, and the study of it likely to lead to some definite conclusions as to the undulatory nature, and even evaluation of the wave-lengths of the X-rays.

Two small Leyden jars then are attached to the Wimshurst in the ordinary way; two well-coiled insulated wires, which are supported on insulating posts, terminate in brass knobs at the ends next the prime conductors of the Wimshurst, and in carefully-made small smooth loops of bare wire at the four ends. There are thus four spark gaps (and it is impossible to overrate the importance of the adjustment of these spark gaps in using the Wimshurst for this, or any other experiments where fluorescent screen or photographic effects are required—why,

will appear later). For brevity I designate the spark gaps thus :—

(N) Gap between negative knob terminal of Wimshurst and coiled wire to kathode.
(K) Gap between coiled wire to kathode and the kathode external wire loop.
(P) Gap between positive knob terminal of Wimshurst and coiled wire to anode.
(A) Gap between coiled wire to anode and the anode's external wire loop.

Experiment i.—Make N and P about ½", A exceedingly small, and K about ¼". The result, when the machine is being turned by hand as quickly as is convenient, is a series of discharges, during each of which the tube flashes out a brilliant, almost orange-green, giving on my fluorescent screen a light so bright as to be trying to the eyes ; the hand will show at once that X_3-rays are being emitted, and with this arrangement I have shown the ordinary shadow experiments to a large room-full at once. Three or four persons can see at the same time the back-bone and ribs of a man if a little care is taken to exclude extraneous light ; and what I expect will interest a great many people who are not scientific, I have seen (to put it popularly, though of course incorrectly) through a brick wall, *i.e.* through 8½ inches of solid brick. To speak exactly—the rays which come through the brick are sufficiently powerful to show dullish flashes on the screen, and a piece of platinum foil placed just behind the screen is distinctly visible, though badly defined, during the flashes. It is necessary, of course, to be careful to avoid any ordinary light reaching the screen, or any X-rays from reaching it except through the wall ; but the experiment has been performed carefully many times now, and there is no doubt whatever as to the power of the rays from even my small tubes to penetrate this thickness of brick. These X_3-rays have wonderful penetrating power, and experiments with them are well worth making. The X-light is able to penetrate a little over 1½" of glass, and 3" of water easily, and 37" of wood.

In this experiment, unless the spark gaps are adjusted carefully (and the measurements I give are only intended as a rough guide), sparks pass along the outside of the tube in a way which at first made me anxious for the tube's life ; but so long as the tube's loops are nearer to the coiled wires than any other part of the tube, experience teaches me there is no danger. Even during the passage of these external and noisy sparks, there is a discharge inside the tube sufficient to show a faint and very transparent hand shadow on the screen, the bones being scarcely distinguishable from the flesh—these being the most transparent shadows I have yet seen.

Experiment ii.—Arrange so that A is exceedingly small, and N and P about equal, and so that the discharge by long sparks along the tube and outside it are just avoided ; then take a piece of thoroughly wet string, and fasten one end of it to the kathode loop, and the other to the end of the coiled kathode wire (a few strands of lamp-wick answer even better), and move the kathode coiled wire away from the tube's neighbourhood, carrying (of course) one end of the string with it until there is no direct sparking through the air, and all the discharge goes through the string. If the radiation from the tube be now examined by the screen with the hand held close behind it, the shadow of the flesh will be very dark indeed, and the bones scarcely visible ; in fact, it is fairly easy to secure a quite black shadow whilst the rest of the screen is brightly illuminated. These are, therefore, the X_2-rays. By shortening the string gradually the shadow changes, the flesh becoming more and more transparent, the bones' shadows remaining black for some time, until when the direct disruptive discharge through the air begins the X_3-rays are immediately restored, and the radiation penetrates easily both flesh and bone. Thus, by "loading" the circuit more or less, the character of the radiation is altered. We know that the discharge of a Leyden jar is oscillatory, and the frequency of vibration very high, also that the frequency is lowered and the oscillations damped by the use of a wet string or other resistance placed in the jar's discharge circuit ; hence it appears reasonable to suppose that it is this slackening of the electrical oscillations which produces the corresponding change in the X-rays, and that this slackening can be produced by altering resistance outside as well as inside the tube, at any point, perhaps, in the circuit, so long as the discharge is kept disruptive in character. In this experiment the discharge through the three spark gaps, and so through the whole circuit, is certainly disruptive ; but the influence of the wet string on the whole circuit, including, of course, these gaps, is shown strikingly by the altered appearance and sound of the sparks at N and P. The wet string, therefore, causes the tube to produce rays of the same kind as the heating of the tube, and if heat increases the general conductivity, it would seem that the wet string must do the same thing. It is, besides, obvious that the wet string takes the place of a rather wide air gap, and it can be very easily proved by experiment that the air gap possesses the greater resistance. Hence it might be thought that the vibrations in the case of air would be more slowly executed ; but in these experiments we have to do, not with the ordinary resistances of air and wet string, but with their resistances during the disruptive discharge ; to put it into popular language, the air can stand a great electrical stress without giving way, but when once its initial and great resistance is overcome, its resistance may be for the time very greatly diminished, so that the electricity surges backwards and forwards, it may be, many millions of times in a second ; whereas in the case of the wet string, although it opposes at first far less than the air, yet its resistance never breaks down completely, for this very reason. The air and the string may be compared in this respect to an oak and a reed in a gale of wind ; the reed, though it bends still resists, is always resisting, and the more it is bent the more it resists ; the oak stands unmoved till it is broken or uprooted, and its resistance overcome. That the oscillatory discharge is necessary for the production of the X-rays I feel no doubt, though it would be an extremely interesting experiment for any one, who had the means and leisure, to try whether they could be produced by a so-called continuous current from a battery. A very few thousands of cells would seem likely to be necessary ; but if any one should construct a tube according to the hints and instructions given in this letter, I think that the number which would be found necessary might be a good deal less. The discharge of a Wimshurst without Leydens, and with the four spark gaps nil, is still disruptive, though I expect less so when (unlike mine) the plates have no metal buttons and sectors on them ; the rotating mirror, I believe, shows that even the silent brush discharge is disruptive—certainly the thin blue sparks are so, and the discharges from the revolving plates on to the combs and between the two plates themselves, are all disruptive.

Experiment iii.—The spark gaps being arranged as in Experiment ii., instead of the wet string the secondary circuit of my 4½" spark induction coil was inserted, the rays given off by the tube were then X_1-rays, which gave most exquisitely bright and clear pictures on the screen, whilst at the same time the discharge through the coil gave rise to very decided Hertz effects for a considerable distance. It is clear that a rheostat of some fine wire of high resistance would be convenient to use with a tube, and that by its means we could adjust the kind of X-ray evolved very nicely.

The nature of the spark discharges at N and P during the emission of the X-rays deserves close attention. At times the spark seems like a string of equidistant silver beads strung on a bluish violet thread, and suggests stationary waves. Perhaps I may add that my work is necessarily interrupted for some weeks at least. I hope that any one who finds in this letter suggestions he would like to follow up experimentally, will not fail to carry out his wishes. The form of kathode I should recommend is a concave mirror focused on the anode, the outer rim being bent back so that the edge is well concealed behind the mirror, a section through the centre of the mirror face having a form something like a very shallow sign of Aries.

Eton College, July 24. T. C. PORTER.

Extension of the Visible Spectrum.

REFERRING to the interesting letter on the above subject, from Prof. Oliver Lodge and Mr. B. Davies, in your issue for the 29th ult., I should like to mention that I have observed a similar extension of the visible spectrum when thrown upon a fluorescent screen of barium platino-cyanide. I may add that a screen of this description becomes brilliantly luminescent when brought into the vicinity of the brush discharge from a large Wimshurst machine, or, better still, from a Tesla coil. In the latter case the fluorescent surface will become luminescent at a considerable distance from the electrical discharge, if facing the latter ; but if the screen is held with its opaque backing towards the discharge, the platino-cyanide will only luminesce if actually penetrated by the streamers of the discharge.

This screen will also fluoresce brightly at several yards distance from an ordinary Geissler vacuum tube.

A striking contrast is afforded by placing a piece of plain white paper over a portion of the screen, and observing the whole by the light either of a Geissler tube or of the Tesla brush.

Under these conditions the white paper will appear very dark, while the fluorescent surface is brilliantly luminous.

A. A. C. SWINTON.

66 Victoria Street, London, S.W., November 3.

IN continuation of our letter of October 29, we find that a reflexion grating does not show the bands so well as a quartz prism, because metals, *e.g.* silver-on-glass, do not reflect all this kind of light completely except at grazing incidence. The furthest band shown by a Rowland grating at incidence 45° has wave-length 2200 tenth-metres, whereas the extreme ultra-violet usually quoted (the Fraunhofer line U) is 2948 tenth-metres, and the bright bands shown by quinine are about 3250 and 3830 respectively. With a quartz prism the fluorescence caused by light of shorter wave-length than 2200 can be seen. But it is quite possible that Sir George Stokes in 1852 saw as far as we can see to-day.

Osmotic Pressure.

As Mr. Whetham has called attention in your columns to my attempt to give a mechanical hypothesis for osmotic pressure, in the October number of the *Philosophical Magazine*, perhaps you will allow me to give some explanation of my somewhat faulty use of the term "dissociation hypothesis," which, as Prof. Ramsay has pointed out to me, may easily be misunderstood. I have used the term to signify not the separation of the ions in electrolytes, but rather the freedom of the solute molecules in non-electrolytes, and of the atoms in electrolytes—their dissociation, in fact, from the molecules of solvent. It appears to me that in some statements of the facts of osmotic pressure, the idea is strongly suggested that the molecules or atoms of the solute are moving about among the molecules of the solvent, and, as far as pressure at any rate is concerned, dissociated from them, and producing an independent effect, the osmotic pressure being directly due to the solute. My aim is to show that we may more reasonably account for the facts by supposing that the solute molecules or atoms are associated with the solvent molecules, entering into some kind of more or less unstable combination with them, and that the solution is not to be regarded as consisting of two parts producing independent pressures. The extra osmotic pressure is, of course, due to the solute in one sense, in that it would not exist without it; but it is an indirect effect, due to the modified compound molecules formed. The first effect is a decrease in "mobility" of the solution, so that the exchange in the two directions through a semi-permeable membrane is unequal, and it is only rendered equal when the solution is put under the extra pressure which we call osmotic pressure.

Mr. Whetham has shown, in a very simple way, that my hypothesis does not necessarily conflict with the facts of electrolysis, and that the idea of dissociation of the ions *from each other* may easily be reconciled with it.

Mason College, Birmingham, October 31.

"Purple Patches."

I SHOULD be very glad if I could obtain information as to the cause and nature of certain "purple patches" which I have noticed from time to time for many years past, but have been unable to get explained. The patches in question occur during, or immediately after, rain, on the pavement or roadway; dashes of vivid purple, or rather violet, varying in size from small splashes or drops to patches as large as the palm of one's hand, but most commonly they are about the size of a shilling. When quite fresh, sometimes a little clot is observable in the centre of the splash. Sometimes I find one patch completely isolated, sometimes two or three in close proximity; sometimes, again, numerous little drops scattered over a certain space; once I counted twenty or thirty tiny dashes in about ten yards of pavement. When quite wet the violet colour can be rubbed up with a handkerchief or paper, which it stains as with "aniline purple" dye, as it does the pavement, and when once dry it is quite inerasible, and lasts till it is worn away by exposure, or the feet of passers-by. I observe it to occur chiefly during warm rain after a dry or cold spell; *never during* dry weather, whether in summer or winter. During the past hot summer there was none to be found, but directly the weather changed in July, I saw it in various localities. This was also the case in the long cold winter of 1895, when on the breaking up of the frost there were plentiful patches to be seen up and down the streets; there was also a complete absence during the following summer, till the drought gave, and then again I found this appearance recur. I naturally observe it most in Bath, where I live; but it is not at all confined to one place or situation. I have found good specimens at such widely different places as the doorway of a hotel at Oban; the Castle Hill, Edinburgh; railway platform at Morecambe; doorstep at Windermere; in streets and roads at Cambridge, Bude, Penzance, St. Ives, Clevedon; once in a London street (Pall Mall East), and once some was found in a cold water bath.

I have from time to time made inquiries from various people who I thought would know, but have not been fortunate enough to meet any scientific person who has observed it. But one learned professor to whom I described the "patches," suggested whether "purple bacteria" would prove a solution to the mystery, and recommended me to inquire through the medium of your columns. I should be much obliged if some one would enlighten me, or mention some authority to whom I could refer.

A. PEDDER.

13 Somerset Place, Bath, October 27.

Note on "Plasmodiophora brassicæ."

ALTHOUGH it is well known that *Plasmodiophora brassicæ* attacks the great majority of cruciferous plants, yet no instance of the common Shepherd's purse (*Capsella bursa-pastoris*, D.C.) being attacked is recorded in this country. Thus Massee (*Proc. Roy. Soc.*, vol. lvii.) quotes the Shepherd's purse as being reported by Halsted to be attacked in America, but says "It has not been observed to be diseased in this country, although one of our commonest weeds." During the past summer my attention was drawn to some plants of *Capsella* with swollen roots, growing in a sandy field near Coventry, on land upon which crops of swedes and turnips were grown in the usual rotation, and I had no difficulty in finding several additional specimens. These roots, on examination, were found to have the characteristic plasmodium in their cells. The Shepherd's purse must now be numbered among the plants in this country which provide a home for *Plasmodiophora*, and probably help it to maintain its existence in the ground from year to year, thus proving a possible source of injury to cruciferous crops.

The length of time for which *Plasmodiophora* can retain its vitality in the soil in the absence of any cruciferous plants, is still a matter of uncertainty. In order to ascertain this, in November 1893, I established a series of experiments (fully described in my annual report to the Newcastle Farmers' Club, 1895), intended to extend over a period of six years. In these experiments, six beds (A–F) and six large 18-inch flower-pots (A–F) were prepared, and each strongly infected with pieces of turnip badly diseased with "Finger-and-Toe," one bed and one flower-pot being sown with turnips each successive spring. The beds and pots acted as duplicate experiments, and the soil in both remained unmanured, and was carefully guarded from the intrusion of *Plasmodiophora*, while all cruciferous plants were rigidly excluded.

In 1894, in both pot A and bed A "Finger-and-Toe" appeared; in 1895, in the pot B "Finger-and-Toe" was found upon four plants out of six; and in the bed B, 8 per cent. were diseased. In 1896 the same result was strikingly shown; after a period of three years, the bed C and pot C were still found to be diseased, four out of five plants being affected in the latter, and 10 per cent. in the former. Massee had previously shown that the germs of disease retain their vitality for two years, and my experiment this year shows that this period can be increased to at least three years.

Sparrows and Wheat.

IN vol. vii. part iii. p. 522 of the *Journal* of the Royal Agricultural Society it is stated that, in the Leicester district, Rivett's wheat is much grown, the reason being that sparrows do not attack it, while they do other varieties. Can any of your readers assign a cause for the exemption from attack of this particular variety? It is most curious if correct; and the authority quoted apparently is a good one.

F. G. BROOK-FOX.

Port Navis Cove, Penryn, Cornwall. November 1.

THE NEWEST GERMAN POLYTECHNIC.

WHETHER there is any sufficient ground for the opinion that Germany, by reason of her superior educational system, is gaining at our expense an undue share of trade and commerce, is a question on which statistics of exports and imports necessarily throw much light, although they fail to completely satisfy those who have watched the recent rapid development of German enterprise. Be that as it may, there can be no doubt as to the efforts which Germany is making to improve her trade by taking advantage of every application of science that may seem likely to help in developing her industrial operations. We are sometimes apt to think that, whilst we are gradually improving our educational machinery at home, Germany is standing still. But this is not so. On the contrary, experience seems to have strengthened her belief in the value of the higher scientific education, and there is no unwillingness on the part of the several German States to incur the expenditure needed to render its benefits readily accessible. The new Polytechnic at Darmstadt is a case in point.

For many years Darmstadt has had in the *Kapellplatz* a technical high school, which had gradually grown in size till it occupied eight separate buildings. Latterly, however, it became too small for the increasing number of its students, and the question of its further extension was carefully considered. The immediate cause, however, of the erection of a new building, was the recent rapid development of the electro-technic school, which, commenced on a very small scale in 1882, has now become the most important section of the new institute. It is interesting to note that we in England were the first to establish a school for the study of the technical applications of electrical science. For a short time the Finsbury College had no rival, and in 1882 the appliances in German schools for practical instruction in electrical engineering were meagre in the extreme. The state of things now is very different, and the institution at Darmstadt is a good example of recent progress.

The necessity for extending the old technical school was soon recognised by the State authorities, who at once offered to provide £16,000 for the erection of special electro-technic laboratories, and £11,250 for equipment.

Simultaneously with this offer came a suggestion from the city of Darmstadt to take over the old buildings in which the Polytechnic had been housed, and to contribute towards the erection of a completely new school the sum of £60,000, it being understood that with the payment of this amount all duties and obligations of the city towards the school should cease. This generous offer was at once accepted by the State, and a site measuring about 24,000 square yards was provided in the beautiful gardens adjoining the city. The preparation of the plans was entrusted to the official State architect, with whom, however, were wisely associated the two Professors of Architecture, Dr. Wagner and Dr. Marx, who had been connected with the school for over twenty years, and were thoroughly familiar with the requirements of the different faculties, and were able easily to ascertain the wants of their several colleagues.

The Darmstadt Polytechnic—Main Building.

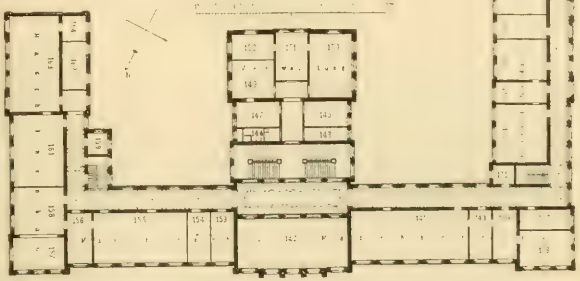
The main building, as shown in the sketch, is three-storeyed, and has a north frontage. There are three wings at right angles to it, which are given up to the teaching of mathematics and some branches of natural science, and to the schools of architecture and engineering. In these wings first year's students receive their instruction. Opposite the front entrance of the building, and on the other side of the road, are two separate institutes—one of which contains the physical and electro-technic schools, and the other the chemical laboratories and class-rooms. In the rear of the main building is the engine-house, from which electric light and power and heat are supplied to all three buildings.

In the fitting and equipment of the several laboratories, class-rooms, and lecture-rooms, all the professors lent their aid, each advising with respect to his own particular department; and to the expert assistance thus obtained is undoubtedly due the completeness and the economy

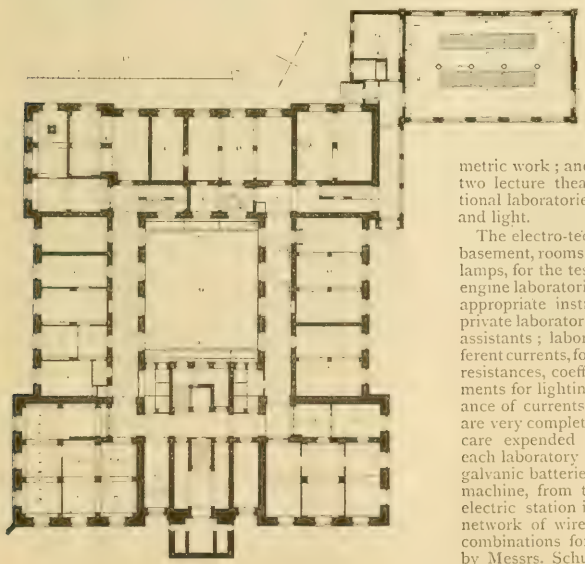
effected in the details of all the arrangements for practical instruction and experimental work. The building was begun in February 1893, and was completed in October 1895. The cost of the entire institute, including fittings, furniture, machinery and apparatus, did not exceed £120,000. The cost of the main building alone was £46,485, which works out to about 5½*d.* a cubic foot; and this gives some idea of the apparently cheaper rate at which such buildings are erected in Germany.

The main building contains the usual series of drawing offices—a special feature of every technical college in Germany—rooms for collections of various models, the engineering laboratories, class-rooms, lecture-rooms, a large hall, a library, and the administration offices. The arrangement of rooms on the first floor, mainly devoted to mechanical engineering, is shown on the annexed plan.

The most interesting department of the institute is undoubtedly the building devoted to the physical and electro-technic schools. This is divided into two distinct sections—the one for instruction in physics proper, including electricity, and the other for the technical applications of electricity. In the annexed plan of the ground floor, the rooms on the left of the central court belong to the physical, those on the right, including the annex containing the dynamo and motor machinery, belong to the technical section. Each section contains workshops for the making and the repairing of apparatus, but these shops are not used by the students. Indeed, workshop training does not, even now, form any part of the curriculum of students at a technical high



Main Building—First Floor Plan.



Ground Floor Plan of adjoining Physical and Electro-technic Institute.

school. They are required however, during their course of study, to spend parts of their long vacations in engineering shops; and no difficulty is found in obtaining for students admission to the State railway works, or to the machine shops of well-known electrical firms.

The apparatus of the two divisions of the physical and technical institute is necessarily, to some extent, duplicated, and the more so, as the schools are kept quite distinct; but there are some advantages in the two departments being housed in the same building. Each department contains separate laboratories carefully fitted for experimental work, and provided with the necessary apparatus and appliances for accurate measurements. In the basement of the physical department is a room specially fitted with double walls for experiments requiring uniform temperature, rooms for chemical and photographic work, an engine-room containing a gas motor, dynamos, and other machines. On the ground floor are separate laboratories for the Professor of Physics, Dr. Schering, and for the chief assistant, a laboratory for magnetic experiments free from iron fittings, and other separate laboratories for galvanic, optical, and photometric work; and above this floor are the balance rooms, two lecture theatres and preparation rooms, and additional laboratories for exercises and experiments in heat and light.

The electro-technic section of this building has, on the basement, rooms for accumulators, for testing arc and glow lamps, for the testing of cables, besides the dynamo and engine laboratories. These are all carefully equipped with appropriate instruments and apparatus. Above are the private laboratories of the Professor, Dr. Kittler, and of his assistants; laboratories for measuring the strength of different currents, for magnetic investigations, for determining resistances, coefficients of induction, &c. The arrangements for lighting the lecture-rooms, and for the conveyance of currents from different combinations of batteries are very complete, and give evidence of the thought and care expended on the equipment of the school. To each laboratory separate currents are supplied from the galvanic batteries and dynamos, from the main current machine, from the accumulators, and from the central electric station in the rear of the main building. The network of wires, which can be connected in different combinations for experimental purposes, has been fitted by Messrs. Schuckert, of Nürnberg, in whose works are found a large number of the students who have received their training at this school.

There are already over three hundred students in this one department of the Darmstadt High School, and

the building, which was completed in October 1895, is now being extended. The course of instruction covers four years: the first year is spent in the main building, in a general course of scientific study; the second is given up to physics, and the last two years are devoted to practical exercises in the electro-technic institute.

The chemical school is housed in another separate building, which also consists of two departments—the one for the study of pure chemistry, and the other for the study of chemical technology, electro-chemistry and pharmacy. The department for pure chemistry consists of three large laboratories for analysis and preparation work, and of a number of smaller laboratories for special researches. It has accommodation for sixty to seventy students. There are separate rooms for thermo-chemical, spectroscopic, photometric, and other physical experiments, as well as rooms for chemical investigations connected with secondary and other batteries.

The other side of the chemical school is mainly devoted to the study of electro-chemistry, and is equipped with the necessary apparatus and machinery, including continuous and alternating current dynamos, for experiments and researches in this special branch of applied chemistry.

The foregoing sketch gives only an outline of the facilities for the higher scientific education which are provided in the Darmstadt Institute, the most recently equipped of the many German technical high schools. The attendance of students during the recent summer semester is given as follows:—

Departments.	Regular students.	Occasional students.	Total.
Architecture	74	13	87
Engineering and machine construction	351	37	388
Electro-technology ...	307	23	330
Chemistry	89	13	102
General science	29	18	47
	850	104	954

In the chemical department, 39 are returned as students in the electro-chemical section.

The teaching staff for these 954 students might seem to us excessive. It consists of 27 ordinary and of 6 extraordinary professors, of 22 demonstrators or instructors, and of 22 assistants, making a total of 77. The students' fees vary from £8 to £12 a year, and the whole of the deficit on the cost of maintenance is defrayed by the State. PHILIP MAGNUS.

A VISIT TO AN ENGLISH WOAD MILL.

A REFERENCE to any old gazetteer under the name Wisbech will show that this town was once an important centre of the English woad industry. It is not generally known, however, that woad is still grown and worked up in a few localities, and it was with some surprise that we learnt that the processes connected with the manufacture might be seen in operation at Parson Drove, near Wisbech, at the present time. There are said to be three other places where the plant is cultivated and worked up for use by dyers—one near Boston and two near Holbeach, in Lincolnshire; but at these centres the introduction of steam power has destroyed the primitive character of the manufacture. As an interesting survival of the past, the mill at Parson Drove is well worthy of a visit.

It is hardly to be expected that a feeble tinctorial substance, such as woad, can retain a permanent footing as an English product in view of the circumstance that it has to compete with indigo, as well as with its modern coal-tar substitutes. The thought that this old-time industry, like the potash-making in Essex,[1] is sooner or later destined to become extinct, has led us to place upon record the information which we gathered during a visit to the Parson Drove mill in July of this year. We may add that descriptions of this mill were given in the *Gardeners' Chronicle* in 1881[2] and 1882; but, as we obtained later and more detailed statements on the spot, concerning the actual operations as now conducted, it may be of interest to chronicle the facts once again while it is still possible to get particulars from the woadmen at first hand.

The leaves of the plant (*Isatis tinctoria*) are wrenched off at the base by the pickers, the root being left undisturbed, so as to permit the growth of a second crop. The first process consists in crushing the leaves to a pulp under rollers. The latter, of which there are three at the Parson Drove mill, are hollow, slightly conical, wooden drums, with about two dozen iron cross-bars arranged round the circumference, these iron bars furnishing the effective crushing edges. The three rollers are geared to a long projecting horizontal pole, which is made to move round by means of a horse. The pulpy mass resulting from the crushing operation is then kneaded by hand into balls, about the size of cricket-balls, on a wooden stage, the balls, when made, being placed in three rows on wooden trays, which, as they are packed, are pushed up a sloping plank till high enough to go on to the head of a man who stands at the end to receive them. Each tray, as it is delivered, is carried to the drying sheds. The balls are allowed to dry in the air for about four weeks, and are for this purpose transferred from the trays to wooden gratings arranged in tiers in the roofed, open framework sheds, known locally as "ranges" (shown in the illustration). When dry, the balls are again ground up under the rollers, and the material then conveyed to the floor of another roofed shed, where it is sprinkled with water, and allowed to ferment for a period of nine weeks. The shed in which this process goes on is known as the "couching-house." The fermenting mass is constantly turned over by the workmen, and water added from time to time. We were told that the fermentation is at first very vigorous, the mass getting quite hot and steaming. At the end of the process in the couching-house the woad is ready for the market, and is simply packed tightly into wooden casks for sending away.

The primitive character of the manufacture makes it not only of interest as a lingering survival of an ancient rural industry, but the antiquarian and lover of folk-lore may derive instruction from the mode of construction of the rough sheds, and from the technicalities used by the workmen. Thus the term "couching" is used in a similar sense by maltsters, and is no doubt a Norman survival (Fr. *Coucher*); the sloping plank is called the "firm" (? form), and the tray on which the pulp is kneaded is known as the "balling-horse." The balls were formerly dried on wattles, known as "fleaks," a term apparently identical with the word still used for hurdles in Scotland; but these are no longer used at Parson Drove. The central circular shed containing the rollers is built of wooden planks and posts, and thatched with a conical roof; the lateral couching-house is constructed of thick turf walls, with the slabs arranged in a peculiar herring-bone form, and also roofed with thatch.

[1] See a paper by Henry Laver in the *Essex Naturalist*, vol. ix. p. 119.

[2] The writer of this article acknowledges, as the source of his information, a recent paper in the *Friends' Quarterly Examiner*. An interesting popular account of the mill appeared in *Aunt Judy's Annual* volume in 1883.

The whole construction was evidently framed with a view to cheapness and simplicity, so as to be easily removable. In the palmy days of the industry the sheds were not permanent erections, but were moved about from one place to another, so as to be near the crops.

We content ourselves with recording the bare facts without comment or criticism. Any science that lurks behind this ancient manufacture has been found out empirically, and handed down by tradition from a remote past. The imaginative person may indulge his fancy by carrying back the woad industry to that period when the early inhabitants of this country furnished that solitary scrap of personal information which is still the historical stock-in-trade of the average schoolboy. It may be well, however, to point out in this connection that *Isatis tinctoria* appears not to be a native of Britain.[1] We were told that in former times the woad-men a zymolytic decomposition of glucosides. The use of woad as a source of indigo is now very limited, being confined to some of the old-fashioned Yorkshire dye-houses, where it is used in conjunction with indigo in the so-called "woad vat," a description of which will be found in any work on dyeing.

FRANCIS DARWIN.
R. MELDOLA.

NOTES.

THE Royal Society's medals have this year been adjudicated by the President and Council as follows:—The Copley medal to Prof. Carl Gegenbaur, For.Mem.R.S., for his researches in comparative anatomy, and especially in the history of the vertebrate skeleton; the Rumford medal to Prof. Philipp Lenard,

Woad Mill at Parson Drove. Two "balling-horses" are shown in front; between them is the "firm," from the further end of which a man is lifting one of the trays on which the balls are carried to the "ranges"; the latter are shown on the right

were limited to certain families, and that they had traditional chants of their own; but these are passing into oblivion, and we were unable to ascertain the words.[2] The object of drying the pulp first, and then wetting it again before allowing it to ferment, is not at first sight obvious, nor could we learn why this practice has been found advantageous. The fermentation itself is no doubt

and also to Prof. Wilhelm Conrad Röntgen, for their investigation of the phenomena produced outside a highly exhausted vacuum tube through which electrical discharge is taking place; a Royal medal to Sir Archibald Geikie, F.R.S., on account of the great value and importance of his many original contributions to geology; a Royal medal to Prof. Charles Vernon Boys, F.R.S., for his invention of quartz fibres and investigation of their properties, his improvement of the radio-micrometer and investigations with it, for developments in the art of instantaneous photography, and for his determination of the value of the constant of attraction; the Davy medal to

[1] In the "Flora of the British Islands" (ed. 1870), Hooker says: "The ancient Britons stained themselves with this plant; later the Saxons imported it." Can it be that even at that remote period the British colour industry could not hold out against continental competition?

[2] A verse is recorded by Miss Peckover in the article in *Aunt Judy's Annual* volume for 1883, p. 549.

Prof. Henri Moissan (of Paris), for the isolation of fluorine and the use of the electric furnace in the preparation of refractory metals; the Darwin medal to Prof. Giovanbattista Grassi (of Rome), for his most important discoveries, especially on matters directly related to Darwin's speculations. Her Majesty has signified her approval of the award of the Royal medals.

WE find the following piece of news in the *Pall Mall Gazette*:—"Prof. Koch and Dr. Kohlenistock, the German bacteriological experts, are to leave Southampton on the 14th inst., in the *Dunottar Castle*, for the Cape. They are being sent out by the German Government to inquire into the plague of rinderpest, and to report what measures are best in their opinion to prevent it spreading to the German South-west African Colonies. The Cape Government is giving every facility to the Commission." Nothing could better show the vast difference which exists between the British and German Governments in relation to all questions of science. We were informed some time ago, by one upon whom implicit reliance can be placed, that some years ago, long before the devastating rinderpest crossed the Zambesi, the Foreign Office was warned of its serious nature, and it was pointed out at the same time that the proper step to be taken was to send out a competent man of science to investigate it, in order that some means might be found to stop it. The Foreign Office declined to take any action in the matter.

AT first sight it might appear that such a question as the election of the President of the Royal Academy is beyond our purview; but there is one point about it, which makes it needful for us to refer to it. The Royal Society and Royal Academy are the bodies in this country to whom is entrusted the duty to look after the highest interests of science and art respectively. It is necessary that in the case of both bodies the office-bearers should be chosen among those whose leadership is beyond question. The distinct affirmation by the Academicians by their selection of the new President, that excellence in art is the chief point they have to consider, should not be without reflex action in our scientific bodies, first among which is our Royal Society. With some of the minor societies excellence in science is oftentimes one of the last things to be considered.

THE following is a list of those who have been recommended by the President and Council of the Royal Society for election into the Council for the year 1897 at the anniversary meeting on November 30:—President: Sir Joseph Lister, Bart. Treasurer: Sir John Evans, K.C.B. Secretaries: Prof. Michael Foster, Prof. Arthur William Rücker. Foreign Secretary: Dr. Edward Frankland. Other names of Members of the Council (the names of new members are printed in italics): *Prof. William Grylls Adams*, *Prof. Thomas Clifford Allbutt*, *Prof. Robert Bellamy Clifton*, *William Turner Thiselton-Dyer*, *C.M.G.*, *Prof. James Alfred Ewing*, Lazarus Fletcher, Dr. Walter Holbrook Gaskell, *Prof. Alfred George Greenhill*, Dr. William Huggins, Prof. Charles Lapworth, Major Percy Alexander MacMahon, R.A., *Prof. Raphael Meldola*, *Prof. William Ramsay*, *The Lord Walsingham*, *Prof. Walter Frank Raphael Weldon*, Admiral William James Lloyd Wharton, C.B.

SIR JOSEPH LISTER and Prof. Michael Foster have been elected honorary members of the Asiatic Society of Bengal, as successors to Huxley and Pasteur.

PROF. PENZIG, of Genoa, has started on a botanical expedition to Buitenzorg, Singapore, and Ceylon. The editorship of *Malpighia* is in the meantime undertaken by Prof. Pirotta, of Rome.

PROF. HUGO DE VRIES has been appointed Director of the Botanic Garden in Amsterdam, in the place of Dr. Oudemans.

THE German Fisheries' Association has offered a prize of 600 m. for the best essay on the history of development and the vital conditions of *Leptomitus lacteus*, with especial reference to its appearance and disappearance in impure water. The essays are to be sent in to Prof. Weigelt, 90/91 Zimmerstrasse, Berlin, S.W., by May 1, 1897.

THE Republic of Mexico, at the beginning of October, adopted the metric system of weights and measures for use throughout the country as a legal system.

A RUN of motor cars from London to Brighton will take place on Saturday, November 14, when the new regulations with respect to the use of light locomotives on highways come into force. The vehicles will assemble at the Hôtel Métropole, and are expected to start at 10.30 a.m., Mr. Henry J. Lawson, President of the Motor Car Club, leading the way. Fifty-four cars have been entered for the trip.

ARRANGEMENTS are now actively in progress at Newcastle-on-Tyne for the opening there, in February next, of an Electrical and Engineering Exhibition, which, among other purposes, is to commemorate the sixtieth year of the Queen's reign. It is proposed to illustrate the changes and developments that have taken place in electrical, engineering, and other leading branches of industry since 1837.

THE College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about 180 dollars, will be made on July 14, 1897, provided that an essay deemed by the Committee of Award to be worthy of the prize, shall have been offered. Essays intended for competition may be upon any subject in medicine, but must not have been published, and they should be received by the Secretary of the College on or before May 1, 1897.

A REUTER telegram from Stockholm announces the death of Prof. Hugo Gylden, the eminent astronomer, at the age of fifty-five. After studying at the University of Helsingfors, his native town, he entered the Observatory at Pulkova, where he was the pupil of Struve. In 1871 he became Director of the Observatory in Stockholm, and, after thirteen years, was appointed to a similar post in Göttingen. He was a member of the Stockholm Academy of Science, a corresponding member of the French Institute, and an officer of the Legion of Honour. His numerous works have made his name very familiar to astronomers.

THE opening meeting of the 143rd Session of the Society of Arts will be held on Wednesday evening, November 18, when an address will be delivered by Major-General Sir Owen Tudor Burne, K.C.S.I., Chairman of the Council. The subject of the address will be "India, its Arts, Manufactures and Commerce." At the subsequent meetings before Christmas, the following papers will be read:—"Recent Developments in Mechanical Road Carriages," by W. Worby Beaumont; "The Teaching of Economics," by W. A. S. Hewins; "Mining at Great Depths," by Bennett H. Brough.

THE *New Bulletin* announces that the Government of Zanzibar have decided to appoint a Director, and have selected Mr. Robert N. Lyne for the post. The new Director informs Mr. Thiselton-Dyer that the object of the Government in creating the post is to improve, where possible, the methods under which the agriculture of the country is now carried on, and to endeavour by experiment to discover some new product that may to a certain extent take the place of cloves. The Government desire that the work so admirably begun by Sir

John Kirk when he was Consul General there, and since interrupted, may be continued.

AT a meeting of the Royal College of Physicians held on Friday last, a Committee was appointed to consider and report to the college on the desirability of including the subject of bacteriology in the course of study and examination for the college licence. The members of the Committee are—Dr. Pavy, Dr. Church, Sir Dyce Duckworth, Dr. Ord, Dr. Poore, and Dr. Washbourn. At the same meeting, Sir William Roberts was announced as the Harveian Orator for 1897; and it was decided that the sum of 1000*l.*, presented by Captain E. Wilmot Williams, with the object of perpetuating the memory of the late Dr. Bisset-Hawkins in connection with the college, be utilised for the purpose of establishing a gold medal to be presented by the college. The medal will be awarded triennially to some duly-qualified medical practitioner who is a British subject, and who has during the preceding ten years done such work in advancing sanitary science, or in promoting public health, as in the opinion of the college deserves special recognition.

A PRIZE of £50, to be called the Welby Prize, is offered for the best treatise upon the following subject: "The causes of the present obscurity and confusion in psychological and philosophical terminology, and the directions in which we may hope for efficient practical remedy." Competition is open to those who, previously to October 1, 1896, have passed the examinations qualifying for a degree at some European or American university. The Committee of Award will consider the practical utility of the work submitted to them as of primary importance. The essays, which may be written in English, French, or German, must be type-written, and extend to at least 25,000 words. They should be headed by a motto, and accompanied by a sealed envelope containing the name of the writer. Manuscript from America should be sent to Prof. E. B. Titchener, Cornell University, Ithaca, N.Y., and must reach its address not later than October 1, 1897.

MR. FRANCIS GALTON traces, in the *Fortnightly Review*, a hypothetical discovery of a system of signalling from the planet Mars, and shows how a succession of signals, divided into dots, dashes, and lines of light according to their duration, might be interpreted. Savages can communicate with one another by gestures, deaf mutes by the movements of the lips, and criminals by alphabetical tappings upon the walls of their cells. Mr. Galton shows how, by a kind of Morse code, the Martians could first signal to us the summation of numbers, such as $2 + 3 = 5$, $3 + 3 = 6$, and also the results of multiplication and division. He does not consider the view of the fourth dimensionists, that possibly there are worlds where $2 + 2 = 3$. After the arithmetical rules had been signalled, the supposition is that the relative distances of the planets from the sun were flashed to the earth; then the relation between the circumference and diameter (π); then the area of the circle (πr^2); then the names of a number of regular polygons, with the number of sides and area of each. Granting that the Martians were able to make themselves clear so far, they could develop a system of picture-writing. With three varieties of signal, twenty-seven combinations would be possible, and each could represent a particular word or sign. Each side of a polygon with twenty-four sides could, therefore, have a name of its own, and each one would have a definite bearing or direction with reference to the others. All is now plain sailing. The Martians signal the symbols of a number of sides, and, as each is received, a line is drawn in a particular direction. From the formula thus obtained, a picture can be reproduced, as Mr. Galton showed at a Royal Institution lecture in 1893 (see NATURE, vol. xlvii. p. 342). The conclusion is that intelligible messages are possible between planets sufficiently near together for signalling purposes.

IN our last issue appeared an abstract of the presidential address delivered by Mr. J. Wolfe Barry, C.B., F.R.S., to the Institution of Civil Engineers, which now numbers nearly 7000 members of all classes. Under the altered by-laws the session of the Civil Engineers commences on the first Tuesday in November, and lasts exactly six months, ending on the last Tuesday in April. By a supplemental Charter, obtained in March last, the number of the Council has been extended in order that all engineering interests, both at home and in the colonies and India, may be fully represented on that body, while corporate members have been given the power of voting for the election of the Council without the necessity of being present at the annual general meetings, a condition which had practically debarred the majority of the members from voting at all. During the past year some important changes in the staff of the Institution have taken place. Mr. James Forrest, who has been connected with the society for fifty-four years, has retired from the post of Secretary, his successor being Dr. Tudsbery. Mr. Forrest has been appointed Honorary Secretary; while the retiring Honorary Secretary, Dr. W. Pole, F.R.S., has been, by a special vote of the Institution, enrolled in the distinguished list of Honorary Members. The following medals and premiums have been awarded by the Council to the authors of papers dealt with during the session 1895-96:—Telford medals and premiums to H. Riall Sankey, late Captain R.E.; Prof. J. A. Ewing, F.R.S., J. O. Arnold, G. H. Hill, and F. E. Duckham; Telford medal and Manby premium to the Hon. R. C. Parsons; Watt medals and Telford premiums to Jeremiah Head, Dr. E. L. Corthell, and C. F. Jenkin; George Stephenson medals and Telford premiums to G. F. Deacon, W. Adams, and W. F. Pettigrew; Telford premiums to John Dewrance and A. F. Bruce; Manby premiums to B. Donkin and Alan Brebner; Crampton prizes to Hammersley Heenan, W. Gilbert, T. Wrightson, H. F. Parshall, and D. T. Jarintzoff, Imperial Russian Navy; Trevithick premiums to A. W. Szlumper and C. A. Rowlandson; and Miller prizes to W. O. Leitch, jun., A. S. Butterworth, E. S. McDonald, S. Thow, J. Scott, J. Andrew, and M. De Ville.

MR. SHELDON JACKSON has filed, at Washington, a report of the condition of affairs in Alaska. Among items of interest are the statement that the Government herd of reindeer has increased in number to 1091; of which 337 are young of the present year, that have not attained sufficient maturity to enable them to endure the rigors of winter. The weather last winter was exceptionally severe, a temperature of $-87°$ having been noted at one point, and $-20°$ having been sustained for a period of several weeks.

NUMBERS of swallows were seen skimming over the river Test, at Mottisfont, Hampshire, on Monday, November 2. Mr. W. C. Worsdell, who imparts this information, says they sometimes rose forty or fifty feet in the air, but for the most part they remained near the surface of the water. Probably this behaviour at a late season induced the old naturalists to think that swallows hibernated beneath the water. On October 27, Mr. Worsdell observed house-martins flying to and fro over Kew Gardens; and on November 1, they were seen flying high in air above the New Forest. Mr. S. Stainer, writing from Southampton, says he saw five swallows briskly flying a little before sunset on November 6.

A RAPID photographic printing machine was shown by Mr. Friese Greene at the Royal Society Conversazione in May last (see NATURE, vol. liv. p. 37). A roll of rapid bromide paper was fed in at one end of the machine, and finished prints were turned out at the other end at the rate of two or three thousand

an hour. In a recent number of the Russian *Photographic Review*, a description is given of the establishment of Arthur Schwartz, at Berlin, where illustrations for magazines are printed by this method. The bromide paper generally employed is 100 centimetres wide and a kilometre long. Sometimes a width of 450 centimetres is used, and full-size photographs of men on horseback have been produced. If the negative from which prints are required is much less than 100 cm. wide, a row of them is arranged; and in this way forty thousand copies of cabinet photographs have been printed and finished ready for distribution in ten hours. Our Russian contemporary gives a photograph printed by the new method, and it is really a very brilliant picture. It is stated that the twelve hundred copies required for the embellishment of the *Review* were absolutely identical in tone and detail.

IN a recent paper communicated to the Academia dei Lincei, G. Folgheraiter describes a curious method he has devised for obtaining the approximate value of the dip in ancient times, and hence deducing the value of the secular variation. In previous papers he has shown that clay, if baked in a magnetic field, becomes permanently magnetised in such a way that its magnetic axis coincides with the direction of the magnetic field. Hence by measuring the direction of the permanent magnetism of clay articles, the date of manufacture of which is known, and on the assumption that they were placed in a certain position when baked, to deduce the value of the dip. With a view of testing the value of this method, a series of preliminary experiments have been made, by baking a number of cylinders and cones of clay in a furnace which was quite free from iron, the test-pieces being placed in positions the relation of which to the direction of the earth's magnetism were carefully noted. After cooling the baked clay test-pieces were placed, with their axes east and west, at a certain distance from a magnetometer, and from the magnitude of the deflections produced when the objects are rotated into different positions, the direction of the permanent magnetism is deduced. The author reserves an account of the results for a future paper.

ATTENTION has lately been directed to the surgical uses of oxygen gas, the treatment consisting essentially in the exposure of affected parts to the action of the gas, either pure or diluted with purified air. An account of some remarkable results obtained by this means is given in a recent number of the *British Medical Journal*, by Mr. George Stoker. Examinations of the bacteriological conditions of affected parts before and after treatment, show that oxygen has a selective action in reference to micro-organisms in the wounds, destroying some and encouraging the growth of others. In all healthy and rapidly healing wounds certain micro-organisms regarded as favourable to recovery are found, while others are regarded as unfavourable micro-organisms. Whatever may be the connection between the organisms and the state of a wound or sore, it seems to be established that when, in a wound treated by oxygen, healing is arrested or retarded, there is always a corresponding decrease of favourable and increase of unfavourable micro-organisms. If the strength of the oxygen bath be increased when this condition arises, the character of the micro-organisms from the wound is entirely reversed. Oxygen thus encourages the growth of micro-organisms characteristic of healing wounds, with the result that a cure is rapidly effected. A long and varied experience of the oxygen treatment has led Mr. Stoker to conclude that the method heals in less time than any other form of treatment, allays pain, stops foul discharges, forms a healthy new skin, and is far more economical and less expensive than any other form of treatment, both as regards suffering and money.

TO the *Revue Générale des Sciences*, of October 15, Dr. Bernard Renault contributes an interesting article entitled "Les Bactéries et leur œuvre Géologique," in which he comes to the following conclusions: (1) That the bones, shells, and teeth of animals in Primary times were infested and destroyed by bacteria, analogous in their form and size to those which, at the present day, produce caries. (2) That formerly the remains of plants were invaded by multitudes of bacteria, some attacking the membranous cellular tissue, and others the thicker portions. Some of the bacteria acted more particularly upon the spores contained in the sporangia of ferns; the parenchymatous tissue first disappearing, then the woody fibres, and finally the cells of the epidermis. (3) That if nothing occurred to arrest the progress of bacteria, every part of plants would disappear successively, and only numerous colonies or zoogloea formed by micro-organisms would remain visible. (4) That these zoogloea often served as centres of attraction for mineral matters, amorphous or crystalline, thus producing oolitic or spherulitic structures in rocks. (5) That coal contains considerable quantities of bacteria, which, by causing the formation of hydrogen and carbonic acid, have brought cellulose and its derivatives to the chemical composition of this combustible." (Even during the preparation of his article, Dr. Renault found micrococci and bacilli in coal from Saint Étienne, Commentry and Vicoigne, in Tertiary coal, and in the coal of Transylvania.) Dr. Renault suggests that the work of bacteria, which goes on in marshes, ponds, &c., was stopped by the rising of water, frequent in Primary times, and capable of carrying away plants, having undergone a more or less complete transformation in lakes of a certain extent, into seas where fermentation became impossible owing to their depth. The physical properties of coal—density, hardness, tenacity, &c.—have, therefore, he concludes, only appeared as the result of a slow compression at the centre of a permeable medium, the compression being due to the various layers which covered the coal.

PROF. H. B. DIXON and H. Brereton Baker have investigated the influence of Röntgen rays on some chemical actions, but from their note, published in the *Transactions* of the Chemical Society, it appears that the results have hitherto been negative. The effect was tried on mixtures of carbon monoxide and oxygen (dried and moist), hydrogen and oxygen, carbon monoxide and chlorine, hydrogen and chlorine, and, lastly, hydrogen sulphide and sulphur dioxide (dried). No combination, either explosive or gradual, occurred between the gases exposed. The combination of chlorine with carbon monoxide and with hydrogen is effected by light, but the addition of Röntgen rays did not alter the rate of combination. Although the rays cause electric discharge from metallic bodies, they appear to have no effect on electrolysis. The action on a photographic plate is probably caused either directly or by the fluorescence of the film. It is not due to fluorescence of the glass, because the deposit of silver takes place entirely on the side of the film exposed to the rays.

THE Royal Meteorological Institute of the Netherlands has recently published a volume containing interesting *Mededeelingen*, or extracts from the log-books of Dutch ships navigating various parts of the world. The extracts include noteworthy phenomena relating to atmospheric electricity, unusual disturbance of the compass needle, volcanic eruptions and earthquakes, icebergs, &c. The first edition of this work appeared in 1867; in the twenty-nine years which have elapsed, a large amount of material has accrued, which made it desirable to recast the whole work, rather than issue a supplementary volume. It may be worth noting that the present work also contains a discussion of meteorological observations made on the Congo, and particulars relating to a few places on the coast of Lower Guinea.

IN the *Indian Meteorological Memoirs*, vol. vi. part iii., 1896, Mr. J. Eliot publishes an important discussion of the hot winds

of Northern India. The chief features of the air movement in the hot weather months of March, April, and May are: (1) A feeble motion during night time, increasing rapidly to about 2h. p.m., and, under favourable conditions, blowing almost with the force of a gale during the next two or three hours; (2) intense dryness and excessive temperature, in which the humidity occasionally falls as low as two or three per cent., and the shade thermometer ranges between 105° and 115°; (3) clouds of dust, which give a peculiar reddish glare to the sunlight. Mr. Eliot shows, from careful comparisons of hourly observations of the various elements, that the more important features of the hot winds are practically identical with the winds of the cold weather months, the difference of their characteristics being chiefly due to the altered climatic conditions of the period.

THE United States Naval Observatory stands in a reservation of seventy acres. The magnetic buildings are on a small knoll surrounded by a deep ravine, and the only disturbances to which the magnetic observations are subject arise from an electric railroad, trolley system, at a distance of 1375 feet from the instruments. The ravine appears to diminish the effect of the railroad, for neither the declination nor the horizontal force instrument shows evidence of disturbance, though the vertical force records are slightly affected. Appendix I. to Washington Observations, 1894, is devoted to the magnetic work at the Observatory during that year by Lieut. C. C. Marsh. All the records are tabulated in periods of 26·68 days, instead of the calendar months, the calendar followed being that drawn up by Prof. Frank Bigelow. This plan has been adopted with the view of further studying the relation between the sun and the earth's magnetism. Several plates accompany Lieut. Marsh's report; and among the subjects illustrated by them are the Observatory grounds and buildings, composite curves of declination and horizontal force, curves of diurnal variations of the magnetic elements, and curves of hourly and monthly disturbances of the declination.

THE atomic weight of magnesium has recently been redetermined with great care by Prof. Richards and Mr. Parker, of Harvard, and an account of their results appears in the current numbers of the *Proceedings of the American Academy of Sciences* and the *Zeitschrift für anorganische Chemie*. The previous determinations of the atomic weight of this element showed a remarkable inconsistency until the year 1884, when Marignac recorded the results of a large number of closely concordant experiments pointing to the number 24·37. The accuracy of this number has now been confirmed by Messrs. Richards and Parker. The method selected was the analysis of magnesium chloride. The salt was prepared, with great precautions, from the double magnesium and ammonium chloride by heating in a current of dry hydrogen chloride; it was then transferred to a weighing tube, without the possibility of contact with moisture, and the chlorine precipitated by silver nitrate, either gravimetrically or volumetrically. The results of four series of very concordant experiments give the number 24·362 as the atomic weight of magnesium when oxygen is taken as 16·00, or 24·179 if oxygen be taken as 15·88.

In the *Zeitschrift für Elektrochemie* for October 5, Messrs. E. J. Constam and A. von Hansen describe the preparation of potassium percarbonate by the electrolysis of a solution of potassium carbonate. It may be assumed that the alkali carbonates, like the salts of other dibasic acids, dissociate in very concentrated solutions more or less completely into the ions M^+ and $MHCO_3$, the latter may, under favourable circumstances, combine, at the moment of their separation at the anode, to form a percarbonate. In order to test this view, the authors have electrolysed a strong solution of potassium carbonate. At ordinary temperatures oxygen is evolved at the anode, and potassium bicarbonate precipitated; as the temperature falls the evolution of oxygen slackens, and at − 10° ceases almost entirely, a bluish amorphous powder appearing in place of the potassium bicarbonate. The best results are obtained with a saturated solution of potassium carbonate at temperatures not higher than − 15°. The current density (from 1 to 300 ampères per square decimetre) appeared to have little effect on the yield. The bluish precipitate is rapidly decomposed by water at the ordinary temperature, and must, therefore, be rapidly filtered off, dried on porous porcelain, and finally over phosphorus pentoxide. It then forms a bluish white, amorphous, hygroscopic powder. It loses carbon dioxide and oxygen when heated; in ice cold water it dissolves without decomposition, but the solution evolves oxygen at the ordinary temperature. It liberates iodine from potassium iodide or hydriodic acid, oxidises lead sulphide to sulphate, decolourises indigo, reduces manganese and lead peroxides, and evolves oxygen when treated with silver oxide. Dilute solutions of caustic potash or of sulphuric acid decompose it with formation of hydrogen dioxide.

THE additions to the Zoological Society's Gardens during the past week include two Chacma Baboons (*Cynocephalus porcarius*, ♂ ♀) from South Africa, presented by Captain Baker; a Grand Galago (*Galago crassicaudata*)) from East Africa, presented by Mrs. Le Poer Richardson; a One-streaked Hawk (*Melierax monogrammicus*) from West Africa, presented by Mrs. Palmer; an Oyster-catcher (*Hæmatopus ostralegus*), European, presented by Miss Beatrix Martin; two Ortalan Buntings (*Emberiza hortulana*), British, presented by Mr. John Young; a Black-eared Marmoset (*Hapale penicillata*) from South-east Brazil, two Choughs (*Pyrrhocorax graculus*), British, deposited; two Black Swans (*Cygnus atratus*) from Australia, two Coscoroba Swans (*Cygnus coscoroba*) from Antarctic America, purchased.

OUR ASTRONOMICAL COLUMN.

MARS.—A Kiel telegram, dated November 11, gives us the following information. "Mars, Trivium Charontis double November 10. Flammarion."

Trivium Charontis is not a canal, but one of those "oases," as Lowell terms them. It forms the meeting point of no less than nine canals, namely: Orcus, Erebus, the twin Hades, Styx, Cambyses, Cerberus, Laestrygon and Tartarus. The observation above referred to is of importance in that Lowell seems never, as far as we know, seen them double. He defines them as being regular both in position and shape. When they form the point of intersection of single canals they appear as round spots, but in the case of double canals "they look like rectangles with the corners rounded off." The most striking case he noticed was the very oasis, Trivium Charontis, that is in question. Lowell found also that the oases "grew" as the canals appeared to grow, so that this observation of Flammarion may be of a special interest as regards the development of this, the largest Martian oasis.

EPHEMERIS FOR COMET PERRINE.—A postal card from Kiel, dated November 7, informs us of the elements and ephemeris of this comet for the ensuing week, computed by Prof. H. Kreutz from observations made on November 2, 4, and 6. These are as follows:—

T = 1897 February 6·819 Berlin Mean Time.

$\omega = 164\ 58'\cdot8$
$\Omega = 85\ 10'\cdot2$ } 1896·0.
$i = 146\ 5'\cdot4$
$\log q = 0\cdot06722$

Ephemeris for Berlin Midnight.

1896.	R.A.	Decl.	Log Δ.	Br.
	h. m. s.	° ′		
Nov. 10 ...	20 9·6 ...	+19 3 ...	0·206 ...	1·0
14 ...	20 5·0 ...	16 12 ...	·219 ...	1·0
18 ...	20 1·3 ...	13 34 ...	·233 ...	1·0
22 ...	19 58·2 ...	11 9 ...	·246 ...	0·9
26 ...	19 55·9 ...	8 55 ...	·259 ...	0·9

Prof. Holden has also communicated elements calculated from observations made on November 2, 3, and 4. These are somewhat different from those given above, but the computed position for November 18 is not far from that given in the above ephemeris, being R.A. 20h. 1·8s., Decl. 13° 57′.

On the 10th the comet was nearly in a straight line, joining δ and γ Sagittæ, being about as far from γ as δ is, only on the opposite side. The motion in declination is in the direction of α Aquilæ, near which star the comet will be found on the 26th.

THE LEONIDS.—In a preceding number of NATURE (vol. liv. p. 623), Mr. Denning gave full information for those wishing to observe this star shower with the naked eye, but, curiously enough, he did not mention the great advantage photography would afford us in obtaining a very accurate determination of the radiant point. One can quite understand that, by placing a small camera on a telescope equatorially mounted, and employing a wide angle lens oriented towards the radiant point, a large space in the sky can be included on the plate sufficient to catch many of the streaks if they be at all numerous. The plates can be changed every thirty minutes or so. It was the intention of the writer of this note, some fourteen days ago, to adopt this principle, and he has already been able to get the necessary apparatus ready. The use of a wide angle lens necessitates that, if an equatorial be used, the camera must be placed at the extreme end (object-glass end) of the telescope, otherwise the opening in the shutters will cut off some of the field, and in consequence neutralise to some extent the value of the wide angle. This was found to be so; but, by the kindness of Mr. J. Norman Lockyer, a siderostat was placed at his disposal. The instrument not having yet been set up since its return from the eclipse expedition, it was erected temporarily in a good position open towards the eastward.

Captain Abney has very generously lent a Cooke's lens, invented by Mr. Dennis Taylor, giving a field of about 75° and of about five inches focal length, so that only now fine weather is required.

It may be mentioned that the current (November) number of *The Observatory* contains an interesting article by Dr. Johnstone Stoney on the "Leonids," in which he quotes an extract from a letter received from General Tennant, who advises practically the same method described above. The appendix to this article contains a reference to the literature on the subject of the Leonids, from which we make the following summary.

Prof. H. A. Newton, *Silliman's Journal*, 1864, vols. xxxvii. and xxxviii. pp. 377 and 53 respectively. Prof. Adams, *Comptes rendus*, March 25, 1867, p. 651, and *Monthly Notices R.A.S.*, April 1867, p. 247. Signor Schiaparelli, *Les Mondes*, December 1866, and beginning of 1867. English outline of Schiaparelli's work, by Prof. Newton, *Philosophical Magazine* for July 1867, p. 34. M. Le Verrier, *Comptes rendus*, January 21, 1867, p. 94. Dr. Johnstone Stoney, *Monthly Notices R.A.S.*, June 1867, p. 271, and *Philosophical Magazine*, September 1867, p. 188.

SUNSPOTS, COMETS, AND CLIMATE VARIATIONS.—A problem of considerable interest is suggested by the paper which Herrn Johannes Unterweger contributes to vol. lxiv. of the *Denkschriften der Math. Natur. Wissen. Classe der Kais. Akad. der Wiss.* of Vienna. The pamphlet, which has been printed separately, is entitled, "Ueber zwei Trigonometrische Reihen für Sonnenflecken, Kometen und Klimatschwankungen," and contains a preliminary statement of the investigation in question. The main result of the work is that there seems to be found a striking similarity between the variations of a certain function obtained from periodic comets near perihelion and the curves illustrating sunspot and climate variations. This function is obtained from a formula (see *Denkschriften Kais. Akad. Wien.*, vol. lix.) that he has previously published, which gives a relationship between the function and the inclinations and perihelion distances of well-observed periodic comets. The comets dealt with are divided into two groups, according as their perihelia lie to the north or south of the solar equator, and the mean of those which pass through their perihelia during each year is taken. The author then finds two trigonometrical series which represent the periods of both sunspot frequency and the variations of this cometary function, the former of which includes a secular variation of about 70 years, while the latter indicates a 35-year variation corresponding with that due to climate variations. In the curves shown, Herrn Unterweger indicates a variation in the minima as well as in the maxima in the case of the calculated frequency of sunspots, the former of which does not really occur as observation shows. The investigation is, however, full of interest, and perhaps the more detailed discussion which he promises will throw more light on this question.

THE EXPLOSIVE PROPERTIES OF ACETYLENE.

IN view of attempts to extend the use of acetylene as an illuminant, the disastrous explosion in Paris, to which reference was made in our issue of October 22, has created a good deal of anxiety in this country. In this connection it may interest our readers to have a further account of the memoir on the explosive properties of acetylene recently presented to the French Academy by MM. Berthelot and Vieille (see NATURE, vol. liv. p. 591).

The authors state that in acetylene at ordinary pressures neither an electric spark, nor a flame, nor an explosion of fulminate will cause more than a local dissociation of the gas (a fact already established by Prof. H. B. Dixon), but that if the gas be compressed beyond two atmospheres, the dissociation, once started, is propagated without sensible diminution throughout the whole mass of gas. In this way dissociation of the gas was effected in a tube 20 millimetres in diameter and 4 metres long. The acetylene splits up into pure hydrogen and a friable mass of carbon, which forms a cast of the containing vessel, and can be withdrawn intact. At a pressure of 20 atmospheres, which is about half the tension of the saturated vapour of liquid acetylene at 20° C., the explosion develops a tenfold pressure, but the rate of propagation is much below that of true explosive wave of such a mixture as electrolytic gas. The temperature due to the explosion at this pressure is calculated to be 2750° C. As the violence of the explosion increases with increasing initial compression, it was to be expected that liquid acetylene would exhibit the character of a "high" explosive. This MM. Berthelot and Vieille have shown to be the case. Eighteen grammes of liquid acetylene exploded in a steel bomb of 49 c.c. capacity by a hot wire developed a pressure of 5564 kilogrammes per square centimetre. This corresponds to an explosion pressure for the liquid alone of about 9500 atmospheres—a value approaching that of guncotton. The decomposition of liquid acetylene by simple ignition is relatively slow, and appears to take place in two stages, one corresponding to the decomposition of the gas, the other that of the liquid. In an experiment where the liquid occupied ·15 of the containing vessel, a maximum pressure of 1500 kilogrammes per square centimetre was recorded.

Experiments were made to determine whether the compressed gas or liquid could be exploded by mechanical shock. The results were, strictly speaking, negative. Neither by fall, nor crushing with a ram, nor by the impact of a bullet which pierced the containing cylinder, was the acetylene exploded. In the case of liquid acetylene, an explosion followed the shock after a short interval, but this was shown to be due to the ignition of the escaping gas, after admixture with air, by a spark from the breaking metal. A small charge of fulminate of mercury fired in the middle of a cylinder of liquid acetylene detonated the liquid, and shattered the cylinder in the manner of a true explosive.

The authors describe the conditions under which danger may arise by casual elevation of temperature during the manipulation of acetylene. In the first place they note that in generating acetylene by the action of a small quantity of water or excess of calcium carbide in a closed vessel, the carbide may become incandescent and lead to the detonation of the gas. At least one accident due to this cause has already been recorded. Sudden compression of the gas in filling cylinders, or in admitting it into a reducing valve, may likewise raise the temperature to the point of danger. A sharp mechanical shock breaking the containing vessel may cause sparks capable of firing the explosive mixture formed by the escaping gas with the external air.

In conclusion MM. Berthelot and Vieille express their opinion

that the dangers of acetylene are not such as to outweigh its advantages as an illuminant. They add that by simple precautions, such as the slow transference of the compressed gas from vessel to vessel, and the careful cooling of the vessels in which the gas is being compressed, the dangers which they have explained may be easily avoided.

The comfort afforded by these concluding remarks is somewhat abated by the fact that the explosion at M. Pictet's factory was subsequent to the publication of MM. Berthelot and Vieille's memoir. There is no occasion for panic, but the matter evidently demands the most careful attention from the authorities in this as well as in other countries. A. SMITHELLS.

THE PRINCETON SESQUICENTENNIAL.

THE celebration of the one hundred and fiftieth anniversary of the founding of Princeton University, held October 20-22, was doubtless, in some respects, the most brilliant and impressive academic event in all American history. Certainly no other celebration can be compared with it than the Harvard Quarter Millennial of 1888. Most of the leading universities, and many of the smaller universities of America, sent their president; Harvard, Cornell, Columbia, Chicago, Johns Hopkins, Pennsylvania, and Toronto were thus represented. Of the great universities in the United States, Yale alone sent a delegate other than the President, who is now abroad.

The visiting delegates from Europe delivered a series of lectures the week before the anniversary exercises. Prof. Edward Dowden, of Dublin, gave six lectures on "The French Revolution and English Literature"; Prof. Felix Klein, of Göttingen, gave four lectures on "The Mathematical Theory of the Top"; Prof. J. J. Thomson, of Cambridge, four on "The Discharge of Electricity in Gases"; Prof. Andrew Seth, of Edinburgh, gave two on "Theism"; and single lectures were delivered by Prof. Carl Brugmann, of Leipzig, on "The Nature and Origin of the Noun Genders in the Indogermanic Languages"; and Prof. A. A. W. Hubrecht, of Utrecht, on "The Descent of the Primates." Among other foreign delegates were Prof. Henri Moissan, of Paris, Demetrius Botassi, of Athens, and Goldwin Smith, late of Oxford.

Among the proceedings was the unveiling of a table in Nassau Hall, commemorative of the change of name of the University from that of the "College of New Jersey," which has always been its official designation, to "Princeton University," which has already long been its popular designation.

Gifts, amounting to 1,350,000 dollars, have been contributed in honour of the Sesquicentennial, and to mark the change in the Institution's title.

The honorary degree of LL.D. was conferred upon the following delegates, among others:—Wilhelm Dörpfeld, First Secretary of the German Archæological Institute, Athens, Greece; A. A. W. Hubrecht, Professor of Zoology in the University of Utrecht; Felix Klein, Professor of Mathematics in the University of Göttingen; Henri Moissan, Professor of Chemistry in the University of Paris, and Member of the French Academy of Sciences; Edward Baynall Poulton, Hope Professor of Zoology in the University of Oxford; Joseph John Thomson, Cavendish Professor of Physics in the University of Cambridge; J. Willard Gibbs, Professor of Mathematical Physics in Yale University, New Haven, Ct.; Daniel Coit Gilman, President of the Johns Hopkins University, Baltimore, Md.; George Lincoln Goodale, Fisher Professor of Natural History, and Director of the Botanical Garden in Harvard University, Cambridge, Mass.; George William Hill, Member of the National Academy of Sciences, Foreign Associate of the Royal Astronomical Society, West Nyack, N.Y.; William James, Professor of Psychology in Harvard University, Cambridge, Mass.; S. P. Langley, Secretary of the Smithsonian Institution, Washington, D.C.; Joseph LeConte, Professor of Geology and Natural History in the University of California, and President of the American Geological Society, Berkeley, California; John W. Mallet, Professor of Chemistry in the University of Virginia, Charlottesville, Virginia; Silas Weir Mitchell, Philadelphia, Pa.; Simon Newcomb, Nautical Almanac, Navy Department, Washington, D.C.; William Peterson, Principal of McGill University, and Professor of Classics, Montreal, Canada; Ira Remsen, Professor of Chemistry, and Director of the Chemical Laboratory in the Johns Hopkins University, Baltimore, Md.; Henry A. Rowland, Professor of Physics, and Director of the Physical Laboratory in the Johns Hopkins University. The degree was also conferred upon Lord Kelvin and Prof. Otto Struve *in absentia*.

One of the most pleasing and hopeful features of the Princeton celebration was the note of peace and good will to all mankind, which such international gatherings powerfully promote. The first sentiment which called out applause was the hope expressed by President Patton in his opening sermon, that the peace and harmony now happily existing between the two great English-speaking nations might henceforth nevermore be broken; and when in the afternoon of the same day Prof. Thomson, of Cambridge, at the reception of delegates, said that he was glad the revolutionary war had resulted in independence of the United States, as he considered that the best solution of the question, and that England, as well as America, now rejoiced in this outcome of the struggle, the applause was unstinted. WM. H. HALE.

THE OPENING CEREMONY OF THE GATTY MARINE LABORATORY, UNIVERSITY OF ST. ANDREWS.

THE formal opening of the Gatty Marine Laboratory, the general arrangement of which has been already described in NATURE, took place on Friday, October 30, by Lord Reay, a former Rector of the University, in the presence of the Principal and Professors, the representatives of various scientific societies, universities, and colleges, and a distinguished company. In his address Lord Reay paid a tribute to Dr. Gatty for his discriminating generosity. He observed that in countries such as France money was more readily forthcoming for science. He spoke in warm praise of the labours of the late Lord Dalhousie in the cause of the fisheries, and pointed out how important scientific knowledge was in regard to fisheries legislation. Moreover, that whatever revelations science has in store for us cannot be evaded. He was inclined to think that a few central institutions thoroughly well equipped, were better than many incomplete and inefficient schools. The work in the Gatty Marine Laboratory would be of a purely scientific character, but it would be of the utmost value to all who were interested in the prosperity of our fisheries. A glance at the papers published since the opening of the old Laboratory in 1884, showed how essential their contents were for those who wish to protect our fisheries, and who often attempt it in the wrong way. He drew attention to the unique position of the University in regard to the study of marine biology.

Prof. Sir William Flower then followed, and he traced the growth of the study of marine animals during the last fifty years. In former days the zoologist had to depend on the rock-pools, or specimens stranded by storms, or had to work on board ship. Especially he pointed out the development of aquaria from their simplest form to the present great tanks. He then adverted to the growth of zoological stations over the world, and considered that St. Andrews, by its work, had come to be a centre for the study of problems connected with the fisheries. Its laboratory was the first that was fairly established in the British Isles; and while he knew that Edinburgh was often called the Athens of the North, he would now say that St. Andrews had many claims to be called the Naples of the North.

The Dean of the Faculty of Arts then presented the following gentlemen for the degree of LL.D.:—Prof. Sir William Flower, K.C.B., F.R.S.; Rev. Dr. Henry B. Tristram, F.R.S.; Prof. Michael Foster, Sec.R.S.; and Prof. Gustave Gilson, Louvain.

Dr. C. H. Gatty then expressed his gratification at the interest taken in the new Laboratory, and handed to Lord Reay a silver key wherewith to open the door.

Prof. McIntosh, on behalf of the University and the scientific workers, conveyed their thanks to Dr. Gatty for his munificent gift.

Thereafter the Laboratory was inspected by the company. In addition to the living animals in the tanks, the walls of the lobby were hung with coloured drawings of marine animals—enlarged to various degrees, and many beautifully and softly painted—all by the late Mrs. Günther. These drawings consisted almost entirely of representations of living forms from St. Andrews

Bay, coloured from life. A few were also hung in each room. In the tank-room were various nets (surface, large mid-water and bottom), circular flounder-nets, mussel and other dredges, mussel and cockle implements, Italian eel-spear, hand-nets, scoops, water-telescope, thermometers (surface, deep-sea, and open-air), sieves, and various models of trawls, crab pots, &c. In the Director's room were the multitudes of preparations connected with the life-histories of the food fishes, rare pelagic forms, such as the larval *Polygordius*, *Mitraria*, *Tornaria*, and the wonderful larva of *Ludia*. In the specimen-room were the type-series of the pelagic fauna of the Bay from January to December, an extensive collection of pelagic ova of fishes from various parts of the eastern and western shores of Scotland, a series of preparations connected with the life-history of the salmon, a reference-collection of invertebrates, including an interesting series of the mussels of the Eden, oysters from the Forth and from Whitstable, a series of fishes, and other preparations.

THE INSTITUTION OF MECHANICAL ENGINEERS.

ON the evenings of Wednesday and Thursday of last week, the 4th and 5th inst., an ordinary general meeting of the Institution of Mechanical Engineers was held in London, the theatre of the Institution of Civil Engineers having been lent for the purpose. The President, Mr. E. Windsor Richards, occupied the chair on both evenings.

There were three papers set down for reading, as follows:—

"Research Committee on the Value of the Steam-Jacket; Experiment on a Locomotive Engine," by Prof. T. Hudson Beare and Mr. Bryan Donkin.

"Transmission of Heat from Surface Condensation through Metal Cylinders," by Lieut.-Colonel English and Mr. Bryan Donkin.

"Breakdowns of Stationary Steam-Engines," by Mr. Michael Longridge, of Manchester.

The two first papers were taken on Wednesday, Thursday evening being devoted to Mr. Longridge's memoir.

The Research Committee on the Value of the Steam-Jacket has been in existence for a long time now, and has proved one of the least, if not actually the least satisfactory of all the research committees constituted by the Council of the Institution. Most of these committees have done admirable work, and added largely to the stock of professional knowledge and accumulated data which engineers have to draw. Steam-jacketing is perhaps the most abstruse question which has been made the subject of an inquiry, comprising, as it does, problems extending beyond engineering proper far into the province of physical science. Nevertheless, in the present day of enlightenment, with the professor so widely abroad, more ought to have been done than has been done by this committee. It would be difficult to select an engine more unfitted for making an inquiry upon as to the value of the steam-jacket than an ordinary locomotive. Its rapid piston speed—or, rather, the high rate of turning—alone is sufficient to render it unsuitable for this inquiry; but, in any case, a locomotive is the most difficult engine from which to obtain experimental data. It is an athletic feat of no mean order to take even indicator diagrams, when one has to hang on to the side of an engine travelling at a speed varying from anything up to sixty, or perhaps eighty miles an hour. Then a locomotive, even with constant train load—a condition which can hardly be ensured in ordinary work—is seldom for five minutes at a time exerting the same power, owing to varying gradient, state of the rails, and force or direction of wind—the latter a most important consideration. Steam may be shut completely off when descending a steep bank, or the regulator may be full open and link in the last notch under exactly opposite conditions. Between these two states we have all grades of linking-up, an operation which so affects the distribution of steam—compression, expansion, &c.—that one would think the steam-jacket would finally give its job up in disgust from fair despair of knowing what it should do.

The result of all this is shown in the report, which possesses the merit of being absolutely honest and straightforward. Four trial runs were made between Manchester and York during ordinary working, with its attendant stoppages and delays. The steam-jacket fitted was of a temporary nature, and the method of testing was to make one run each way with the jackets in steam, and a like number of runs with the jackets empty. Coal was weighed and feed-water measured by a Siemens' meter. Mr. Michael Longridge drew off samples of chimney gases for analysis. Jacket-water was also drawn off and measured. Speed was taken by a Boyer recorder, and the revolutions assumed from its records.

In spite of the fact that we know nothing more about the value of the steam-jacket than we did before the experiments were made, the trials added, as a by-product, something to the knowledge of railway engineers on the performance of the locomotive; but, in any case, the thanks of the Institution are due to the authors of the paper for their disinterested labours.

The second paper was a complement to the first; for the rate of transmission of heat to and through metal is the chief thing necessary to be known for determining the value of steam-jacketing of engine cylinders. The problem is a vexed one, and no inquiry yet made has taken us beyond its threshold. The authors have attacked the subject by an endeavour to ascertain the actual temperature in the interior of the metal, and by observing the exact appearance of the film of water deposited, and, further, by determining whether such a phenomenon as cloudy steam really exists. Their apparatus consisted of a strong vertical glass cylinder about $5\frac{3}{8}$ inches in diameter and $2\frac{3}{4}$ inches high. Inside this was placed a metallic cylinder. The annular space between the glass cylinder and the enclosed metallic cylinder was filled with steam, whilst through the interior of the metal cylinder an ascending stream of cooling water was made to circulate. In order to determine the thermal gradients in the metal, when its thickness allowed of so doing, the temperatures of the interior were taken in vertical holes 1/8 or 1/16 of an inch in diameter, drilled at different distances from the condensing surfaces, and filled with mercury, into which slender thermometers were inserted. Illustrations of the apparatus were hung on the walls of the theatre, and will be reproduced in the published volume of the *Transactions* of the Institution. The pressure of steam, volume and temperature, of circulating water, and other trial conditions were controlled by suitable apparatus. The first result arrived at was that the authors consider it was not possible to trace the slightest appearance of cloudiness or mist, or of water suspended in the body of the condensing steam. The water of condensation was deposited on the surfaces. A reproduction was given of a photograph of the film of water on the surface of smooth cast-iron as it appeared through the glass cylinder, the steam pressure being 20 lbs. per square inch, and the rate of condensation somewhat slow.

The velocity of circulating water varied between 0·032 and 0·415 feet per second. The different metallic cylinders tried were made from cast-iron with both rough and smooth surfaces 11/32 and 31/32 of an inch thick, copper, and brass with smooth surfaces 2/32 of an inch thick, and smooth steel 1/32 and 10/32 of an inch thick. The rate of heat transmission was found by observing the rise of temperature in a known quantity of circulating water, and by noting the weight of steam condensed. Corrections were made to allow of accidental losses. Without publishing the diagrams on which the results of the experiments were plotted, it would be impossible to give details of the observed results unless we printed the voluminous tables attached to the papers. The greatest quantity of heat transmitted per second was about thirty-five thermal units, and the least seven thermal units per square foot of internal surface of cylinder. The authors consider that the film of water deposited by condensation, and adherent to a metallic surface, resists the transmission of heat in exactly the same way as an equivalent greater thickness of metal would do. The thickness of the water films, as determined by the difference of temperature, is less on a smooth surface of cast-iron than on a rough one, and is apparently not affected by the admission of steam-jets to sweep the surfaces. There is, the paper says, no apparent difference in the resistance to transmission of heat between the surface-layer of metal and the next to it; or, in other words, there is no drop in temperature on entering or leaving the metal. The thermal gradient at any point in the metal would be uniform in a flat plate, and becomes steeper towards the interior of a hollow cylinder as the circumference diminishes. At any point on the surface of the metal next to the circulating water, the temperature, owing to an adherent film in which the thermal gradient exists, is much in excess of the mean temperature of the circulating water at the same point.

In the discussion which followed the reading of this paper,

Mr. Longridge said that the observed result of the steam being not cloudy, all the moisture being concentrated in a film on the walls of the cylinder, would materially affect the conditions involved in passing steam from a jacket to a cylinder, as the steam would not carry condensed water with it. Mr. Halpin questioned the fact of there being no additional resistance to the transmission of heat owing to multiplication of surfaces. The authors' statements on this point are opposed to the opinions held by many engineers; and even if they are right in regard to areas absolutely in metallic contact—like floating surface plates—those perfect conditions are not present in practical engineering work.

The second evening of the meeting was devoted entirely to Mr. Longridge's paper; a most useful contribution to the *Transactions* of the Institution, although not very easy to follow without the aid of illustrations. The paper dealt with 1000 break-downs of factory engines which had come before the author's notice. These Mr. Longridge had analysed and classified in order to show which parts of the engines gave way first, and as far as possible the causes of failure were stated. In some instances the author suggested steps which should be taken to avoid similar mischances in the future. The thousand break-downs were divided into 23 groups, and these were again sub-divided into divisions. Thus there were 213 accidents due to the giving way of "valves and valve gear," and in these were included the giving way of 46 valve spindles, 24 eccentric straps, 23 rocking shafts and levers, 21 nuts, cotters, and pins, 18 eccentric rods, 17 slide valves, besides other parts of valve gear in lesser proportions. It is notable, considering how much dread some millowners have of the "clattering Corliss gear," that only seven accidents are chronicled against this method of steam distribution, especially when one remembers how largely it is now used in Mr. Longridge's district of Lancashire. Valve spindles break when screwed, and this fact leads the author very properly to exclaim against the use of V-threads. Gas threads, he says, are better; and round threads best of all. The sharp V-thread is like the commencement of a tear. Next to valve gear "spur wheels" come on the list, with a total of 124 accidents. Mr. Longridge only includes wheels on the crank shaft; if he had taken second-motion shafts, the total would have been incomparably greater. Back-lash is the most fruitful source of mishap with toothed wheels, and a most fruitful source of back-lash is placing spur gearing and rope or belt pulleys on the same shaft, when the second motion shaft is apt to overrun the main shaft. Uniform load, a heavy fly-wheel, and slow speed of ropes, are points that need to be observed in such cases. Vibration is also a frequent cause of accident with spur gearing. Machine-moulded teeth are best, and it is desirable to carry the toothed quadrants on the arms of the fly-wheel rather than have teeth on its periphery. Air-pump motions are next; they caused 121 breakdowns. The chief heading in this division is "weakness, wear and tear, or neglect"; causes which speak for themselves.

Air-pump buckets and valves were responsible for eighty-eight out of the thousand accidents. These mishaps were mostly due to the giving way of parts, foot-valves being the chief delinquents. In reference to accidents through broken packing rings in buckets, the author said he would as soon have plain buckets, packing rings being "expensive, dangerous, and entirely useless." One speaker, Mr. Saxon, who himself has had considerable experience with mill engines in the same district, agreed with the author in regard to low lifts, but if a high lift were required, he considered packing necessary. "Columns, entablatures, bedplates, and pedestals" accounted for eighty-six break-downs. The settlement of foundations is the most frequent cause in this division, and the author warns engineers against setting-up holding-down bolts in columns when the masonry settles, as this naturally brings undue stresses upon the structure of the engine. The difficulty is that engineers very often do not recognise that the masonry foundations are settling when a column becomes loose on its seating. The chief cause of the decay of foundations appears to be the deterioration of stones, and cement or mortar by oil getting to them. One speaker during the discussion—Mr. Rounthwaite, a marine engineer—asked why the designers of mill engines were so fond of brick-work, and suggested that it would be preferable if very deep cast-iron bedplates were used so as to reduce the masonry required. The author said that the gradual spread of the vertical or inverted type of engine facilitated the use of deeper metal bedplates. The horizontal engine had held its position so firmly because it gave a long stroke, but with the speeding up of mill machinery, characteristic of modern practice, a higher rate of revolutions was required, and this made shorter stroke engines preferable, so that the vertical type was gaining ground. Main shafts were the cause of forty-nine accidents, some of them the most interesting of the series. By far the greater number of shafts that broke down gave way through wear and tear. One veteran made 176 million revolutions before being taken out, owing to a mysterious grooving under an eccentric sheave. A Whitworth fluid-compressed steel shaft gave poor results, running only 61½ revolutions, and giving way under the low stress of 4600 lbs. per square inch. This single case, however, will not be sufficient to destroy the high reputation of Whitworth shafts. Connecting rods, of which forty-one gave way, break almost invariably in the connections, gibs cotters, open-ended straps or bolts giving way; one instance of a body failure, through an imperfect weld, alone being recorded, although there were six failures of forked ends. Cylinders and valve chests, with which there were thirty-five accidents, mostly break on flat surfaces, covers, or doors; the presence of water being the chief cause. Parallel motions account for thirty-five breakages, mostly in eye shafts. Governors supplied twenty-eight accidents to the list, and piston-rods twenty-seven; cotter-holes being again the weak point. The author very rightly warns designers against abrupt changes of section in piston-rods, for though the average draughtsman appears to be quite alive to this evil in regard to castings, yet he often appears to think it produces no bad effect where the effects of unequal cooling are not to be anticipated. Piston-rod crop-heads afford twenty-seven examples of break-downs, mostly from "wear and tear"; the giving way of pistons supplies an equal number of mishaps, whilst the breaking of links contributes twenty-one accidents towards the total.

Nineteen break-downs of fly-wheels are recorded, the chief cause being internal stress—due presumably to ill-proportioned castings—whilst eight bosses were cracked, five by driving keys too hard. The author made some pertinent remarks on the question of keying fly-wheels on to shafts, describing the Lancashire method of "staking," which is the best plan for giving a true running and rigidly secured wheel without straining the boss. Mr. Holroyd Smith, in the discussion, sketched an improved form of key which appeared to be designed on sound principles. Air-pumps and condensers gave way thirteen times, gudgeons in beams twelve times, and cranks twelve times. Of the latter eleven were of cast-iron, so there is not much need to comment upon them. Eleven crank-pins broke; in one case a Whitworth steel pin gave way through the skin being injured by shrinking in the crank web. The tear being started, failure was but the result of time. There were only six instances of broken engine beams. One the author attributes simply to fatigue. The engine was made in 1847 and worked until 1892, when some fine cracks were noticed near the middle of the beam, which was of cast-iron. These cracks developed, extended, and joined up, so that the beam was condemned. Prof. Hudson Beare joined issue with the author on the propriety of attributing the failure of this beam to fatigue. He said that once the original crack was set up, the beam was in a less advantageous position to bear the load put upon it, so that the crack would be further developed until it finally succumbed.

The remaining causes of accident were failures of slide-bars five, and of ropes three; whilst an "entire smash," no cause ascertained, completes the roll of a thousand break-downs.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following science teachers in the University were, on November 7, elected members of the Council of the Senate: Alex Hill, M.D., Master of Downing, and University Lecturer in Advanced Anatomy; R. T. Glazebrook, F.R.S., Assistant Director of the Cavendish Laboratory; and A. E. Shipley, University Lecturer in the Morphology of Vertebrates, and Secretary of the Museums Syndicate. Dr. R. C. Jebb, M.P., and Dr. J. N. Keynes, Secretary of the Local Examinations Syndicate, were also among the successful candidates.

The Professorship of Surgery has been again suspended until the first day of next term, to give time for the further consideration of the stipend and conditions of tenure. It appears

probable that an effort will be made to obtain at once the full stipend of £500.

Dr. J. T. Bottomley, F.R.S., has been appointed an Examiner in Physics, and Mr. L. Fletcher, F.R.S., an Examiner in Mineralogy, for the Natural Sciences Tripos.

At St. John's College, the following awards in natural science, for candidates not yet in residence, were made on November 9: O. May, Tollington Park College, and G. A. Ticehurst, Tonbridge School, Foundation Scholarships of £70 a year; L. Lewton-Brain, Firth College, Sheffield, Foundation Scholarship of £50 a year; L. Miall, Yorkshire College, Leeds, Minor Scholarship of £50 a year; A. J. Harding, Christ's College, Brecon, Johnson Exhibition.

Prof. A. C. Haddon, of the Royal College of Science, Dublin, has been approved for the degree of Doctor of Science.

We regret to announce the death, at Naples, on November 8, of Mr. J. E. Gray, of King's College, Harkness Scholar, who had just been appointed to occupy the University's table in the Zoological Station under Dr. Dohrn.

At St. John's College, the subjects included in the examinations for Entrance Scholarships and Exhibitions in Natural Sciences held in and after 1897 will be Chemistry, Physics, Zoology, Botany, Physiology and Physical Geography. Copies of the new scheme showing the scope of the examination in Chemistry, Physics, Botany and Physical Geography, and including specimen papers in Zoology and Physiology, may be obtained on application to any of the Tutors—Dr. Sandys, Dr. Donald MacAlister, or the Rev. C. E. Graves.

THE East Riding County Council have decided to devote £2000 of the grant received under the Local Taxation Act, 1890, to the relief of the rates. We looked for better things from Yorkshire. The action affords another argument in favour of a Bill for securing the whole of the "whisky money" to education.

DONATIONS amounting to about four million dollars have recently been conferred on, or promised to, the University of California; the largest gifts being from Mrs. Phebe Hearst, widow of the millionaire Senator. The money is to be paid after the State has expended half a million dollars in erecting new buildings. Mrs. Hearst has sent a note to the trustees, enclosing 15,000 dols. to be used in securing plans for the buildings. The architects of all nations will be invited to compete and to submit plans for a group of buildings of similar design, which will surpass anything of the kind in the world. Mrs. Hearst stated that she would erect two buildings at her own expense, one of which would be a memorial to her late husband.

WHEN it was decided to do something for technical education, six years ago, no worse blunder was ever committed than that of entrusting to newly-created Technical Education Committees the whole of the funds arising from the Customs and Excise dues, instead of allocating a definite proportion of the money to the already existing University Colleges, and for scientific investigation. The result of the neglect is that several of the University Colleges are continually in need of funds, and their development is checked on all sides by the ogre of expense, while Technical Education Committees in different parts of the country have a difficulty in spending the moneys under their control. The University College at Bristol is an example of an institution which has suffered, rather than profited by the Local Taxation Act of 1890. The Calendar shows that complete instruction for the London University degrees in science, art, and medicine, can be obtained at the college; and systematic instruction is given in those branches of applied science which are more nearly connected with the arts and manufactures. The results obtained, and the constitution of the professoriate, are sufficient evidence of the thoroughness of the instruction given; yet the college has practically no endowment—a paltry £75 a year, and that derived from a fund started by the students, and called "The Students' Endowment Fund." The other sources of income are: £1200 from the Government, £500 from the Bristol Town Council (for the maintenance of ten free students), £100 from the Company of Clothworkers, a few odd amounts, and the balance from students' fees. The income from annual subscriptions amounts to about £600. It is hardly necessary to say that the college cannot be kept going on such a small budget. Last year the accounts showed an adverse balance of £950, and a total indebtedness of more than £6000, part of which is due to a decrease of the Sustentation Fund, while the rest has been spent in building. An appeal for £10,000 was made in the early summer, and £8044 has been collected, £2000 of this being contributed by the Bristol Town Council, on condition that it should be used in the building of an engineering wing, which has now been completed, and was opened last week. There still remains £2000 to be collected if the college is to be kept out of debt; and we trust that some of the rich merchants in Bristol will subscribe this amount in recognition of the valuable work done, and of the high reputation the college has earned. If any of the great Livery Companies of London are looking for a worthy object to take under their fostering care, as the Drapers' Company have taken the University College at Cardiff, we commend to their attention the University College at Bristol. Two or three weeks ago the Home Secretary held out hopes that there would be an increase of the grant which the State now gives to University Colleges; and this assistance, when it arrives, should place the college at Bristol in a more satisfactory position, though it will not do everything. Never has it been more necessary than now that the various professions and industries should receive the benefits of special scientific education. To let institutions where sound secondary and university education can be obtained be perpetually struggling for existence is, therefore, to neglect one of the most, if not the most, important branch of our educational system.

SCIENTIFIC SERIALS.

Bulletin of the American Mathematical Society, vol. iii. No. 1.—The number opens with an account of the third summer meeting of the Society, which was held in the week after the meeting of the American Association for the Advancement of Science, in deference to the desire expressed by that body. The titles of the papers read, and abstracts of them follow. We give the ensuing abstract of Prof. J. McMahon's paper on the hypothesis of the successive transmission of gravity, and the possible perturbative effect on the earth's orbit. Suppose that the sun is moving in a straight line with velocity u, and that the whole system shares this translatory motion. Suppose, also, that the gravitational influence issues continually from the sun in waves that move outward with velocity v (perhaps equal to the velocity of light), and that when any wave reaches the earth the latter is attracted towards the wave-centre or point of space from which the wave issued. This effective centre of acceleration is at a distance from the sun, which varies between the limits $ka\,(1-e)$ and $ka\,(1+e)$ where k is the ratio of u to v, a is the semi-axis major and e the eccentricity of the earth's orbit. Then the orbit of the earth relatively to the sun is that which would be due to a centre of force that performs small oscillations about its mean position. The law of this oscillatory motion was determined, and the equations of acceleration of the earth in its orbit, along and perpendicular to the radius vector, were corrected for this small disturbance. Appropriate solutions of the resulting differential equations were given as far as terms in k^2. The most important perturbative terms were examined, and their effect on the orbit determined.—"Celestial Mechanics" is a review, in Prof. E. W. Brown's exhaustive style, of astronomical papers prepared for the use of the American Ephemeris and Nautical Almanac (vols. v., vi., vii.; Washington, 1894-5).—Especial attention is directed to a result obtained in a memoir by Prof. Newcomb. "If the coefficients in the time in the arguments and of the periodic terms in Delaunay's results were all expressed in terms of L, G, H, a', e', the perturbations due to the indirect actions of the planets would be obtained by merely inserting the variable instead of the constant values of a', e'." Prof. Newcomb remarks that this curious theorem may embody some principle applicable to the disturbed motion of three bodies which has not yet been fully mastered. It seems probable, in Prof. Brown's opinion, from the way in which the result has been obtained, that it is a direct consequence of the use of canonical equations, and of the form in which the time appears in the result. The notes are very full, as also is the list of new publications.

Wiedemann's Annalen der Physik und Chemie, No. 10.—Measurement of low temperatures, by L. Holborn and W. Wien. Baths of pure liquid oxygen are very constant, and may be used for maintaining a temperature of $-182°$ C. Liquid air changes from $-189·1°$ to $-184·8°$ in half an hour, owing to the evaporation of the nitrogen. Oxygen with 7·6 per cent. nitrogen boils at $-183·2°$ under atmospheric pressure. Higher temperatures may be maintained by melting ethylbromide ($-129·5°$), ether ($-117·6°$), carbon bisulphide ($-112·8°$), methyl formate ($-107·5°$), toluol ($-102·0°$), and ammonia ($-78·8°$).—Tem-

peratures inside vacuum tubes, by R. W. Wood. These are measured by a platinum spiral acting as a bolometer. At an internal pressure of 0·3 mm. the rise of temperature ranged from 13° to 25·7° C. as the current varied from 0·0015 to 0·0036 amperes. At greater pressures the variation for the same current was higher. The author measured the temperatures of the bright and dark spaces by mounting the spiral on a glass arm penetrating into a Torricellian vacuum, and passing down through the mercury and up through the tank. This arm could be shifted up and down without interfering with the vacuum. In every case, the bright spaces were a few degrees hotter than the dark ones.—Electrostatic deflection of kathode rays, by G. Jaumann. When a quiet line of light is produced in a vacuum tube by a feeble current, it may be temporarily deflected by moving a rubbed glass or ebonite rod in its neighbourhood. The author used an influence machine driven by an electric motor as a generator, and immersed a pear-shaped tube in oil, with the anode outside in the liquid, and not fused into the glass. A spot and a ring are produced opposite the kathode, and the former is deflected as described. As soon as the motion of the electrified body ceases, the spot returns to its first position, after a few oscillations. This phenonemon is quite distinct from the permanent deflection produced by neighbouring conductors.—A simple method of separating alternating discharges in vacuum tubes, by R. Hildebrand. Describes various arrangements of tinfoil and other conductors producing permanent deflection and curvature of kathode rays, such as are usually produced by magnets. Also confirms Jaumann's observations of temporary deflections by electrified rods, but uses an induction coil as a source.—The foundations of electrodynamics, by E. Wiechert. Introduces the conception of a rotor as representing the magnetic displacement instead of a vector, and proves its utility in explaining Röntgen and aberration phenomena.—Some properties of Röntgen rays, by A. Winkelmann and R. Straubel. Attempts to discover refraction by prisms of iron, copper, zinc, silver, lead, and platinum failed. The refractive index of iron for X-rays does not differ more than 0·00005 from unity, and is smaller, if anything. Exposures for shadowgraphs may be considerably lessened by placing the sensitive plate face downwards upon a plate of fluorspar.—Wave-length of Röntgen rays, by L. Fomm. A diffraction experiment gave 0·000014 mm. as the upper limit of the wave-length. This is about fifteen times smaller than the smallest ultra-violet wave-lengths hitherto measured.

SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, October 21.—Prof. Raphael Meldola, F.R.S., President, in the chair.—Mr. J. J. Walker exhibited a specimen of *Emus hirtus*, L., taken at Gore Court Park, Sittingbourne, Kent, on May 30 last.—Mr. W. B. Spence sent, from Florence, for exhibition, some specimens of a cricket, *Gryllus campestris*, in small wire cages, which he stated were, in accordance with an ancient custom, sold by the Italians on Ascension-day.—Mr. F. Enock exhibited a specimen of the curious aquatic Hymenopteron *Prestwichia aquatica*, ♀, which Sir John Lubbock, F.R.S., first captured in 1862, but which had not been recorded since that date until its rediscovery in May 1896. Mr. Enock said that the male had remained unknown until June last, when he captured several swimming about in a pond at Epping. The male was micropterous, and, like the female, used its legs for propelling itself through the water.—Mr. Tutt exhibited a beautiful aberration of *Tephrosia bistortata* (*crepuscularia*), in which the ochreous ground-colour was much intensified, and the transverse shade between the median and subterminal line was developed into a brown band; the transverse basal, median and subterminal lines on the fore-wings, and the median and subterminal lines on the hind-wings, being particularly strongly marked in dark brown. Mr. Tutt also exhibited the cocoons, pupal-skin and aberrations of the imago of *Zygæna exulans*. The cocoons were spun upon one another, five in a cluster, and Mr. Tutt stated that the species was exceedingly abundant in the pupal and imaginal stages during the first week of August on the mountain slopes above Le Lautaret, in the Dauphiné Alps, at from 7000 to 9000 feet elevation. The pupa-skin was very similar to those of other Zygænids. The imagines exhibited were all aberrations.—Dr. Sharp, F.R.S., exhibited a caterpillar which had received the eggs of a parasite on the anterior part of the body, the abdomen, nevertheless, went on to the pupal metamorphosis, while the head and thorax remained attached to it in the caterpillar stage. He also called attention to some peculiarities in the pupa of *Plusia moneta*; in this species the pigmentation varies greatly in extent, and is sometimes entirely absent.—Mr. Blandford called attention to the recent discoveries relating to the Tsetse fly, made by Surgeon-Major Bruce in Zululand, which proved that this insect affected animals by injecting them with a parasitic Protozoon. The parasite was communicated from wild animals to domestic animals, and was more widely distributed than was generally believed; it, or a closely allied form, having been found in India and England in sewer rats. He said that Surgeon-Major Bruce had proved that the Tsetse fly was pupiparous, which was of importance as affecting the classification of the Diptera. Dr. Sharp said that in his opinion the Tsetse fly would cease to be troublesome with the advance of civilisation.—Mr. C. G. Barrett exhibited the pupa-skin, cocoon and eggs of *Hesperia comma*, L., found on chalk hills near Reading. He also exhibited and remarked on a series of both forms of *Tephrosia crepuscularia* and *T. biundularia*, showing an unbroken line of variation from brown to white and also to grey and black. In addition, he showed several second brood specimens of both forms obtained in the past summer by Mrs. Bazzett, of Reading.—Mr. Tutt read a paper entitled "On the specific identity of *Canonympha iphis* and *C. satyrion*," and exhibited a long series of specimens.—The Rev. T. A. Marshall communicated a paper entitled "A Monograph of British Braconidæ. Part vii."—Mr. T. D. A. Cockerell communicated a paper entitled "New Hymenoptera from the Mesilla Valley, New Mexico."—Mr. E. Meyrick contributed a paper entitled "On Lepidoptera from the Malay Archipelago."—Dr. Sharp read a paper by Mr. G. D. Haviland and himself entitled "Termites in Captivity in England.'

Royal Microscopical Society, October 21.—Dr. R. G. Hebb, Vice-President, in the chair.—The diploma and medal awarded to the Society for photomicrographs exhibited at the Columbian Exhibition, Chicago, was laid on the table.—Lieut.-Colonel Siddons exhibited and described a new portable dissecting stand, and also a lens-carrier for use as a dissecting microscope.—Mr. C. Beck made a communication on the new screw-tools for objectives.—Prof. F. J. Bell reported that the microscopes of historical interest belonging to the Society had been exhibited at a conversazione of the Pathological Society, and were now on view.—Mr. J. Butterworth read a paper on a photomicrographic camera designed chiefly to facilitate the study of opaque objects, illustrating his remarks by a series of lantern slides shown on the screen.—Mr. T. Comber read a paper on the occurrence of endocysts in the genus *Thalassiosira*.—Mr. G. Murray detailed some observations made in connection with this subject.—Mr. F. Chapman gave a *résumé* of the ninth part of his memoir "On the Foraminifera of the Gault of Folkestone."—Mr. E. M. Nelson read a paper on a method of measuring the apertures of objectives.

MANCHESTER.

Literary and Philosophical Society, October 20.—Mr. Charles Bailey, Vice-President, in the chair.—Mr. A. Griffiths read a paper on concurrent observations of viscosity and electric conductivity of a salt solution containing gelatine, which was allowed to set slowly at a constant temperature. He finds that the resistance does not appreciably alter even when the viscosity becomes very great. Mr. Griffiths subsequently communicated a note on the resistance of a conducting jelly, containing iron filings, in the magnetic field. He finds that a resistance so constituted becomes less by 25 per cent. in a field of 2000 C.G.S. units.

PARIS.

Academy of Sciences, November 2.—M. A. Cornu in the chair.—On the disaggregation of comets, by M. O. Callandreau. The disaggregation of a comet swarm is found to depend on its density and on the nature of its path, being more marked in an elongated orbit.—The gyroscopic horizon of Admiral Fleuriais, by M. E. Guyou. A description of the adaptation of the gyroscope by the late Admiral Fleuriais for giving the vertical plane at sea. It possesses considerable practical advantages over the pendulum, and is particularly serviceable in places where the horizon is hidden by haze or fog, but where the sun can be seen. The rotation of the earth is clearly indicated by this instrument, and a small correction has to be made on this account.—New

researches on the tubercles of the Leguminosæ, by M. C. Naudin. After reviewing the theories of previous workers on the fixation by free nitrogen by the tubercles in the Leguminosæ, the results of experiments are given in which plants were grown from seed in sterilised earth. In many cases the plants germinated five or six days sooner than plants grown in ordinary, non-sterilised earth, and were stronger, greener, and flowered sooner than the latter. The conclusion is drawn that the germs of the tubercle (bacteria, spores, or mycelium) must have been present in the seed or its envelopes. Many of the Leguminosæ, however, are refractory to infection, and it is suggested that the fixation of nitrogen may be a property of the protoplasm of the plant itself.—Note by M. E. Perrier, accompanying the presentation of the fourth part of his "Traité de Zoologie."—M. Duclaux submitted a work entitled "Pasteur, histoire d'un esprit."—On the production of floods, by M. Tarry.—The causes of universal attraction; the ether and the law of gravitation, by M. A. Baudouin.—Surface tension, by M. Langlois.—Note on the satellites attributed to the planet Venus, by M. Triboulet.—Note on storms, by M. Bougon.—On the deformation of surfaces, by M. Paul Stæckel.

Some applications of a theorem, by N. Peterson.—On the theory of partial differential equations of the second order, by M. E. Goursat.—Linear forms of the divisors of $A^2 \pm A$, by M. P. Pepin.—On the gyroscopic horizon of Admiral Fleuriais, by M. A. Schwerer. The results of experiments carried out at sea show that the maximum error in the determination of the altitude of the sun was 2′, while the mean error was less than 1′. After more than forty observations no appreciable wear of the pivot could be detected.—On the Röntgen phenomena, by M. B. Buguet.—On a method of measuring the temperature of incandescent lamps, by M. P. Janet. The method depends upon the assumption that the filament is pure carbon. The total heat lost by radiation between the maximum temperature attained by the filament and that of the air is measured, and the results of M. Violle on the specific heat of carbon are applied to this.—Measurement of the force acting upon non-electrified dielectric liquids placed in an electric field, by M. H. Pellat. Two vessels containing the liquid are connected, one being placed in the field and the other outside of it, and the alteration in the levels measured. The differences observed, which are very small ('06 mm. and under), agree with the calculated figures within the limits of experimental error.—On the heat of formation of lithium hydride, by M. Guntz. The heat of formation was found to be 21·6 calories, a magnitude in keeping with the great stability of the substance. A repetition of the determination of the heat of solution of lithium in water, showed the number previously obtained by Thomsen (49·08 calories) was too low, the correct figure being 53·2 calories. The difference is due to the presence of impurities in the metal used by Thomsen. At its melting point, 680°, the dissociation tension of lithium hydride is about 27 mm., showing a marked difference in this respect from the hydrides of sodium and potassium.—The uniformity of distribution of argon in the atmosphere, by M. Th. Schlœsing. Samples of air from very different sources showed a remarkable uniformity in the percentage of argon, the average value being 1·184 per cent. of the total volume of nitrogen and argon.—On a method of reproduction of double silicates of potassium and other bases, by M. André Dubois.—On French essence of roses, by MM. J. Dupont and J. Guerlain. Whilst samples of French attar of roses of two successive years agreed generally in properties, they differed from a Bulgarian sample in containing more stearoptine.—Development of *Lithocystis Schneideri*, a parasite of *Echinocardium cordatum*, by M. L. Léger.—On a viviparous ephemerid, by M. Causard. Specimens of *Chloeopsis diptera* lived over three weeks after being captured, but in spite of their relatively long life, they do not appear to take more food in the adult state than other ephemerids.—Homology of the anterior segments of some sedentary annelids, by M. Pierre Fauvel.—The use of the X-rays for anatomical researches, by MM. Ch. Remy and G. Contremoulins. By injection of the vascular system with metallic bronze powder, it is made opaque to the X-rays, and in this way it is possible to study the development of bone and teeth with greater certainty and precision than by dissection.—On the mode of formation of the Pyrenees, by M. P. W. Stuart-Menteath.—On some quaternary deposits near Eyzies, by M. Emile Rivière.—Note on some properties of numbers, by M. Delauney.—On earth tremors, and on the relations which exist between cyclones and sunspots, by M. Zenger.—On the red colour of vine leaves, by M. Levat.

THE FORCE OF ONE POUND.

Elements of Mechanics. By Thomas Wallace Wright, M.A., Ph.D. Pp. v + 372. (New York: Van Nostrand. London: Spon, 1896.)

THIS is a good elementary treatise; not too elementary, and yet a book that hard-working students may use from the beginning of their studies. It is a pity that the author ignores altogether the sort of work that is now getting to be very common, even in the older universities—experimental laboratory work in mechanics—but we have here an excellent text-book, even for students who are following an experimental course.

The author wisely assumes that some knowledge of the calculus may accompany a very elementary acquaintance with algebra and trigonometry, and he introduces calculus symbols freely in places where other authors are apt to evade their use, through a wrong notion that two pages of algebra and Euclid afford better mental training than a line of integration. I think that he is right, for every student possesses the fundamental idea of the calculus, and knows the use of squared paper before he knows algebra, and it is very easy to teach him the use of the symbols of differentiation and integration. The more advanced subjects include S.H. motion, forces in hinged structures, moments of inertia, D'Alembert's principle, the dynamics of rigid bodies, strain and impact. The exercises are very numerous; most of them are good, and many of them are of an original and taking kind.

On the other hand, I must say that I could not have believed the book to be a new edition of an older work, had the author not made the statement. It is in need of much correction, and not only of printer's errors, such as errors in decimal points. Then there is a mistake calculated to work great harm at page 12, line 6; the curve representing velocity of a piston as ordinate and space as abscissa, ought not to be like a curve of sines or cosines, being really nearly circular. Such mistakes as "That this principle (the independence of forces in producing accelerations) is not axiomatic, is evident from the opinion of Descartes . . ." (page 49), are, I believe, due only to careless writing; for the author surely does not mean that the opinion of Descartes settles the matter. There is a different sort of carelessness in (page 62, line 17) "At the close of the last century, in different parts of the world, the word *pound* was applied to 391 units of weight, . . ." The author means "391 different kinds of unit. . . ." As the book is not a metaphysical treatise, it seems hardly fair to put before a student the exercise, "Discuss the argument of Zeno of Elea against motion"; "Since an arrow cannot move where it is not, and since it cannot move where it is, it therefore follows that it cannot move at all." There is a reference for help to vol. iv. page 263 of Carlyle's "Friedrich"; but as I have only one edition of Carlyle, the reference is not of much value. The author is disappointing in his *parallelogram of forces*. Seeing that all metaphysical proof has failed, we must frankly adopt the plan of T and T', and say that the parallelogram of forces is included in Newton's laws of motion. It is interesting to note the disappearance, from all books, of the older proofs of fundamental principles which used to form so large a part of the student's work. They were generally based upon the assumption that because we could not conceive of something or other, therefore it could not exist; thus giving a premium to the limitation of our faculties. The method of reasoning is still much followed, but it is not usual to state it so ingenuously; Maxwell uses the method twice in his "Matter and Motion." In page 80, the author takes a line E F to represent the "force of the wind" (whatever that may be, outside the leading article of a daily paper), and he says that the component G F of E F, perpendicular to the sail, is the effective component in propelling the ship. These statements are wrong in such various ways that it might be thought they could do no harm, but in truth statements could hardly be framed to do more harm. The exercise in which a student is asked to criticise Hiawatha's achievements, reads as if the author had not made any attempt to understand the most transparent of poets; and I am sorry to say that some others of the original exercises are really only enlivening because they show that, like Silas Wegg, the author is fond of "dropping into" literature.

If there are these faults, how does it come that I like the book, and recommend it for the use of students? Because it is the work of a man who really thinks about the pedagogy of science; and a man who really thinks, is not to be met with every day; he is a good teacher, even if there is a mistake in every page. The author knows his T and T' well (I imagine), and does not much depart from their excellent methods. The book is one of the best introductions that I have seen, to the study of applied mechanics, and therefore, as an engineer, I like it. It has the fault (to me), but in a less degree than all the best English treatises, of being what is sometimes called "orthodox" in regard to the "British unit."

I think that the only act of the late Prof. James Thomson which was not altogether excellent, was the invention of the word "poundal." But he did not invent the unit to which the name is given; the inventor of the unit has caused it to be true that students are never *sure* in their dynamics calculations. Engineering students dare not for their lives speak of foot-poundals of work and poundals of force among workmen or foremen; and in what place these quantities are familiarly used or needed, except examination rooms, I do not know. To support an artificial and unnecessary system, the old and excellent term "the force of a pound" is maligned in every text-book. It is said to be a variable unit, and according to the definitions of its enemies, it is a variable unit. As if when I say that a certain force is a pound, I mean the gravitational force on a certain piece of metal if it were on the moon or at the centre of the earth. When an engineer says that the pressure of steam is 100 pounds per square inch, there is absolutely no vagueness about his statement. For twenty-six years I have used as my unit of force the gravitational force *at London* on a certain piece of metal called by law a weight of one pound, kept in London. My unit of mass is the mass to which unit force gives an acceleration of 1 foot per second per second, and my students use these as engineers' absolute units. When they are told "a

projectile is 20 lbs., and moves with the velocity of 1000 feet per second," before they start on their dynamical work they say: the mass or inertia in engineers' units is $20 \div 32{\cdot}18$, and they use $\frac{1}{2}mv^2$ and get their answer at once—not in foot-poundals or other absurd units—but in the foot-pound units in which they think and talk. Such students have no troubles and make no mistakes, for they use an absolute system in which their answers are in the language of their daily life, and not *Choctaw*. Clerk Maxwell said, "In fact, the only occasions in common life, in which it is required to estimate weight considered as a force, is when we have to determine the strength required to lift or carry things, or when we have to make a structure strong enough to support their weight." Very well then, in the "common life" of an engineer these are the most frequent occasions. He almost never needs to speak of the inertia of a body by itself; when he needs the idea, it is when on his way to a calculation of force or energy. The physicist uses the other set of so-called absolute units, the C.G.S., and cannot make mistakes: all the other readers of books on dynamics, almost all the readers of Maxwell's "Heat," in which the above passage occurs, are engineers. And all such engineers as do not openly scoff at the teaching of science colleges, have had their lives filled with worry through the misery of having to use the poundal in examinations, and of hearing men who know nothing about engineering or engineers, or their lives or their needs, declaiming against the want of scientific knowledge shown by the engineer. The evils created by mere want of humour in a few influential men have been very great. These men speak of the pull of a tram-car in pounds, and their students need to use pounds of force continually in their laboratories, and they never by any chance use the poundal, or need to use it, except in working academic written answers to academic questions, and in working with an Atwood's machine. When a student speaks of so many pounds of sugar or coals, he is not thinking, nor does he need to think, about its inertia, and the use of the pound in this connection could do no harm, even if g varied ever so much more than it does on the surface of the earth. I see no great objection to the use of the word *weight* as meaning the attraction of the earth for a body, anywhere. Of course this is a variable force, and for practical purposes the weight of a pound anywhere on the earth is a force of one pound.

We are always being told that the pound is legally a quantity of stuff, and so it is; but note the actual wording of the Act, "The weight in vacuo of the platinum weight declared to be the imperial standard shall be the legal standard of weight. . . ." Now I would ask whether the inertia of the standard body is different in vacuo from what it is elsewhere. But I refrain from trying to take an advantage from the wording of the Act; and besides, I do need for my case the words inserted after vacuo "in London," if the legal weight is to be taken as the force of one pound. As the standard piece of metal is kept in London, and is not likely to rust or decay, and possibly its inertia keeps constant and is not affected by temperature, as Prof. Fitzgerald has suggested, perhaps we may concede the following as a definition of our absolute unit of force: the force of one pound is that which would give to a body of 32·18 times the inertia of the standard object kept in London, an acceleration of 1 foot per second per second.

If, however, engineers are to undergo any continuation of the persistent scorn of the last thirty years, let our scorners show some scientific knowledge of our position, and let us hear no more of the engineers' unit of force being the force of gravity anywhere or everywhere upon the standard weight.

As for our useful term *centrifugal force*, even our worst opponents are beginning to find out that there was a third of Newton's laws of motion, and that we may ask: If a body is acted upon by centripetal force, there is an equal and opposite force acting; and if it is not the body that exerts this force, what is it? If the body exerts this force, surely we have a right to call it the centrifugal force of the body.

I would, therefore, make an appeal to our academic enemies: Your students are nearly all young engineers of one kind or another. Why not be satisfied with teaching them about absolute units only—the C.G.S. and the foot, second, force of one pound, system?

You now use three others: the so-called British or poundal system, the gramme gravitational and the pound gravitational systems. It is only, after all, an error of judgment, like the crime of Surajah Dowlah or the St. Bartholomew, and you probably do not know what a complicated mess you make of a young engineer's mind; and we are quite willing to imagine that it is only ignorance and prejudice, and not antagonism to education that impels you to retain this want of system. But one effect is this. Your finished engineering students cannot get into works without paying high premiums; such is the prejudice of the experienced engineer against college-bred men, a prejudice which I myself would again have if I were again to act as a manager of works.

Every now and again an academic friend will say such things as these, "Well, if he cannot take in these ideas, he is not fitted to be an engineer." "If he has all that difficulty about Euclid, he is not fitted to be an engineer." And these academic statements are made about young men who are heaven-born engineers, fellows who never tire of fiddling with engineering things, and who are sure to succeed in actual engineering work, and who, when they do succeed, will scorn the idea that there is any use in a scientific education, and "what for no?" I am very thankful that entrance to all professions is not by examination. Our friends, worshipping the German soul-destroying educational fetish, insist on the very worst system of education for the average Englishman; and when a healthy young soul refuses to be destroyed, you punish its owner by shutting him out of the very professions for which he is best fitted by your wretched examinations. You say he cannot think, and you actually make him believe it too, because he refuses your Duchaylus' proofs and the metaphysics of Alexandrian philosophers. He ought, I suppose, to be grateful that you do not insist on his spending a year in learning the Trireme method of multiplication, or what right he has to say that one line is twice the length of another. Alice's White Knight was not more protected from imaginary dangers than the young men who now are being prepared for their life's work by a wasteful and pedantic trifling

with the metaphysics of physics: Euclid, logic, and the snakes of Iceland!

Although I feel so strongly about the necessity for experimental or kindergarten methods of education being adopted, I do not wish to blame the author of this book. Teachers of mechanics will find it an excellent text-book. JOHN PERRY.

THE FORMATION OF THE FAMILY.

Die Formen der Familie und die Formen der Wirthschaft. Von Ernst Grosse. Pp. 245. (Freiburg and Leipzig: Mohr, 1896.)

PROFESSOR GROSSE, as appears from his preface, took up the anthropological problem of the development of the family, but soon judged the preliminary studies as yet available to be insufficient to enable him or any one else to carry out such a task. Therefore, as a contribution to the work, he set himself to examine the relation of the family systems of the world to one great factor of civilisation, namely the provision of subsistence. The task was judiciously chosen, and students will acknowledge that in his attempt to carry it out, Prof. Grosse makes a contribution of value to the clearing and ultimate solution of the problem. His plan is to divide mankind according to their "Wirthschaft," or economic life, into five classes—the lower and higher hunters, the herdsmen, and the lower and higher agriculturists. He then examines the correspondence between these stages of society and the different forms of family, class, and tribe. At the outset this comparison tells against a state of matriarchal anarchy having ever prevailed among the human species. The low tribes subsisting by hunting, fishing, gathering wild fruits and digging roots, a condition which apparently represents that of primitive man, tend to live in separate small families under a rude patriarchal system extremely unlike promiscuity or communal marriage. Prof. Grosse is enabled by this evidence to fall into line with the increasing number of anthropologists who reject theories of primitive promiscuity. Among modern systems of social development founded on this chaotic basis, that of Morgan in his "Ancient Society" is here mentioned as the most eminent, with a remark which will somewhat surprise English readers, that it has given the American sociologist a place of honour among the Fathers of German Social Democracy (p. 3). In England it is doubtful whether the artificial social scheme of Morgan's later years ever made converts to any serious extent, notwithstanding our high regard for his early work of observation and collection of facts. Considering that Morgan was an adopted Iroquois, living in a Seneca tribe for years as one of themselves, the statement here made (p. 152) is quite inadmissible, that his description of the Iroquois clan-system, which was the starting-point of his anthropological work, was founded on the remarks of Father Lafitau in the last century. Passing on to the chapter in which Prof. Grosse deals with the lower agricultural tribes, we find an important addition to the theory of the maternal or matriarchal system. As hunting and herding belong to the men, so at first agriculture belonged to the women, as it still does among the less civilised peoples. Out of the plant gathering, which is the business of savage woman, arose the invention of agriculture. On this reasonable hypothesis Prof. Grosse accounts for the unquestionable fact that among the Iroquois the women were owners of the soil they tilled and the crops they reaped, and that similar cases are still to be met with among the Balonda in South Africa and the Kocch in Bengal, always in connection with inheritance on the mother's side. As Prof. Grosse reasons (p. 160), we have here a state of things out of which the maternal family, growing into the maternal clan, would naturally arise. The present reviewer has of late years advocated the opinion that the maternal form of society is mainly connected with the husband not taking his wife to his own home, but living in her family, so that her side of the house naturally prevails (see *Nineteenth Century*, July 1896). It is obvious that wherever the land belongs to the women, this would especially tend to happen. As, however, the maternal family and clan appear already among hunting tribes who do not till the soil, it is plain that the full origin of the matriarchal system cannot be sought in the modes of subsistence which come within Prof. Grosse's method of comparison. The same is true of the custom of exogamy, prevailing as it does among hunters, herdsmen, and tillers of the soil. Prof. Grosse's incidental remarks on exogamy, as derived from aversion to marriages of near kin, need not be criticised here, the value of his work being rather in his systematic comparison between the economic and the social sides of human life, which leads him to the conclusion that in every form of culture that form of family organisation prevails which is adapted to economic relations and wants (p. 245). Readers who cannot accept so extreme a claim for the effect of these economic influences, will at least admit their great importance.

EDWARD B. TYLOR.

OUR BOOK SHELF.

Annales de Géographie, No. 23.—*Bibliographie de l'Année* 1895. I. Partie générale; II. Partie régionale. Avec un Index alphabétique des auteurs, analysés, et cités. Pp. 288. (Paris: Colin, 1896.)

THE problem of bibliography threatens to become the most absorbing practical question for all scientific workers. It is not yet quite the time to discuss a proposition to sweep away all previous records and begin afresh; but the time has come for at least producing some sort of classified subject index to all branches of contemporary work. The editors of the *Annales de Géographie*, the foremost French journal of scientific geography, have brought out as their September number a bibliography of geography for 1895. This does not profess or attempt to be exhaustive, but the 1087 titles recorded have been carefully selected, and nothing of the first order of importance seems to be omitted. Notes are appended to each title, not in the nature of criticism, but simply as an indication of the contents of each book or memoir; and these notes are admirably done. They are the work of forty-nine contributors, and each is signed.

The division of the subject is primarily into general and regional geography. The former is divided into *History of Geography; Mathematical Geography; Physical Geography*, subdivided into geology (*i.e.* in its geographical aspect) and orography, climatology, botanical geography, zoological geography, oceanography, rivers and lakes; and *Political Geography*, under the heads races, states

and nations, movements of population and colonisation, products and means of communication, methods of teaching and general works. These, however, only account for 239 titles; by far the greater part being classed under the continents. Europe is apparently the subject of the greatest amount of geographical work (the entries refer to maps and statistics as well as to written memoirs), Africa comes next, and all the rest of the world is dismissed in the same space as was required for Europe alone. This is perhaps the result of being somewhat more exhaustive in treating the countries of the predominant continent.

The bibliography is well planned, executed with praiseworthy impartiality; but for the language in which it is written it might, so far as a reader can detect, have been compiled in any capital of Europe or America, and considering the keenness of national spirit in many of the articles classified, this is high praise indeed.

Animals at Work and Play; their Activities and Emotions. By C. J. Cornish. With illustrations. Pp. 323. (London: Seeley and Co., Ltd., 1896.)

In a previous little volume Mr. Cornish gave an account of life at the "Zoo," in which he called attention to the tastes and preferences of animals for colour, music, and perfumes. In this volume he deals, for the most part, with some of the general activities and emotions of the every-day life of some mammals and birds. Most of the papers, here collected into a well-illustrated and pleasantly-written volume, have appeared from time to time in the columns of the *Spectator*. They cannot be said to contain much that is new, but many of the facts recorded are placed in a new light. There is a wealth of apt quotation, and, without aiming at technical description, the main facts are well put.

To give the reader an idea of what he may find in this work, we may refer to the chapters on "Animals' beds." More might have been made of this subject; for, without venturing on the somewhat mythical subject of the beds said to be built by the anthropoid apes, the beautiful nests of the field-mouse might, with others omitted, have been alluded to. The "Emotion of grief in animals" is another subject admitting of an expanded treatment; indeed, though the chapters are, from the point of view of a weekly journal, all that could be expected, yet in their new form, and remembering the interest of their themes, most of them might most advantageously have been added to.

The full-page illustrations are good; those from a Japanese source, such as the one with the "social sparrows," are excellent.

Model Drawing and Shading from Casts. By T. C. Barfield. Pp. ix + 92. (London: Chapman and Hall, Ltd., 1896.)

It is hardly possible to draw accurately what is seen without knowing why the group or scene being delineated presents the appearance it does. This book will give students a clear idea of the field of view, and, by acquiring from it a knowledge of the laws and limitations of vision, they will be able to make model drawings intelligently.

A Short Catechism of Chemistry. Part I. By A. J. Wilcox. Pp. 16. (London: Simpkin, Marshall, Hamilton, Kent, and Co., Ltd., 1896.)

The worst way to teach science is by catechism, for it leads to belief in doctrines on the authority of the book, while experience and demonstration are neglected. For this reason, we think the compiler of these fifty questions and answers would have done chemical science better service if he had refrained from publishing them. The incorrectness of several of the definitions confirms us in this opinion.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Austro-Hungarian Map of Franz Josef Land.

With reference to Prof. Copeland's letter in your last issue, I must say that I am inclined to believe that Austria Sound will eventually be found to be more or less as Payer originally laid it down. I am inclined to this belief because it seems to me almost impossible that the map of the very track he trod should show any great error. Of course, the longitude laid down may well be erroneous—considering the circumstances—and we may expect rectification of this.

But I am not disposed to pass over the description which Payer gave us of Zichy Land with so light a touch as Prof. Copeland. For, however unintentional his error may have been, there can be no doubt that Payer has misled Arctic geographers into supposing that Zichy Land was a large mass of land. And belief in this, derived solely, of course, from Payer's description, induced Jackson to make certain modifications in his equipment and plans, which are naturally unnecessary now that he has proved Payer's description of Zichy Land to be inaccurate.

For Payer wrote thus of Zichy Land in his "New Lands within the Arctic Circle," vol. ii. p. 206.

"My attention was directed chiefly to the southern parts of Zichy Land, which formed a vast mountainous region beyond Markham Sound. Half the horizon was bounded by cliffs and heights gleaming with snow. The conical shape of the mountains prevailed here also; the only exception was Richthofen Spitze, the loftiest summit, perhaps, we had seen in Franz Josef Land, which rose like a slender white pyramid to the height of about 5000 feet."

Now, as every one knows, Jackson has travelled north across the "vast mountainous region" of Zichy Land, and found that all the time he was marching on sea-ice. He camped where Richthofen Peak is marked in Payer's map, and he was *still on sea-ice*. Richthofen Peak consequently disappears; but Jackson, having robbed Richthofen of his peak, has given him a cape (700 feet high) which is very near the site of the vanished peak.

To put it briefly, in fact, Zichy Land turns out to be a chain of small islands, on the west of Austria Sound, and these islands are of no considerable height. Westward of the chain, Jackson has discovered another Austria Sound, but wider and more important, and this he has named "the British Channel"; while to the north of this channel he has discovered a sea which is open both in winter and summer, and which now owns the name of "Queen Victoria Sea." Zichy Land is, in fact, no longer existent as a "vast mountainous region," and in its place we find a few islands, a wide channel, and a permanently open sea. And these, of course, completely alter the complexion of Jackson's work—the first part of which is to explore and map the Franz Josef Land Archipelago.

No doubt, as far as I can gather, has ever been thrown upon Weyprecht's valuable work. Jackson has, of course, not gone near the locality where Weyprecht observed, and consequently the accuracy or inaccuracy of Weyprecht cannot and does not enter into Jackson's map. But, on the other hand, I do not doubt that my absent friend entertains the highest respect for him, seeing that he has given to a bay he has discovered in the west of the archipelago the name of Weyprecht Bay.

Tournefort and the Latitudinal and Altitudinal Distribution of Plants.

Tournefort has generally had the credit of being the first to indicate a parallelism in the latitudinal and altitudinal distribution of plants; yet it would seem without sufficient ground. Linnæus mentions ("Flora Lapponica," Proleg. n. 14) that certain plants grow on Mount Ararat as well as in Lapland. Later (in 1751), in his "Oratio de Tellure Habitabili" ("Amœnitates Academicæ," ii. p. 447) he distinctly connects Tournefort with latitudinal and altitudinal distribution of plants, and in such a way as to convey the impression that it was

Tournefort's idea. Here follows the paragraph :—"Memoratu dignissimum est, quod refert in Itinerario suo Orientali *Tournefortius:* reperisse se nimirum apud radices Ararati montis plantas illas quæ in Armenia erant vulgares: aliquantum progressus illas invenit, quas in Italia ante viderat: altius scandenti offerebantur Vegetabilia circa Lutetiam Parisiorum crescentia: Plantæ Succicæ erant superiori loco positæ. Sed summum montis locum proxime ad culmen, nive obtectum, plantæ illæ occuparant, quæ sunt alpibus Helveticis et Lapponicis domesticæ."

Humboldt, writing in 1816, "Sur les lois que l'on observe dans la distribution des formes végétales," p. 2, attributes the idea to Tournefort, and its development to Linnæus. Schouw ("Grundzüge einer allgemeinen Pflanzengeographie" (1823), p. 21), almost repeats Linnæus, but uses fewer and somewhat different geographical names. Edward Forbes ("Memoirs of the Geological Survey," i. p. 351) also attributes the idea to Tournefort; yet, as Sir Joseph Hooker states (NATURE, xxiv. p. 444), I also have been unable to find any such idea expressed in Tournefort's works. Indeed, his account of his ascent of Mount Ararat, as given in the English edition of his travels, and verified for me by Mr. Daydon Jackson as being essentially the same in the French edition, is about as weak and silly a piece of writing as one could well find, and quite unworthy of a man of his reputation. True, he mentions a few plants; but not a word on their distribution, except that some of them were common and familiar. No Alpine plant is included in his meagre list. Instead of being a sober narrative of the journey, it is an attempt to be serio-comic with witless allusions to Noah's ignorance of the French language, &c.; and how the travellers filled themselves with water before starting, because none was to be had on the mountain, and their inability to climb in consequence; how they descended on their backs by the hour, and when they were tired of that they turned over face downwards, and other equally senseless and improbable things. It is only fair to add, however, that Tournefort's travels were published after his death, and probably contain matter that he would have expunged.

So far, then, as the evidence goes as between Tournefort and Linnæus, the latter originated the idea, and on very slender materials, if taken from Tournefort, of parallelism in latitudinal and altitudinal distribution of plants. Considering, too, that Linnæus was born only a year before Tournefort's death, it is difficult to find any other explanation.

Kew. W. BOTTING HEMSLEY.

The Work of Local Societies.

MAY we beg a small portion of your space to give publicity to the accompanying circular, which is being issued to all the local scientific societies in the United Kingdom? An abstract of Mr. Abbott's scheme was published in NATURE of October 29 (vol. liv. p. 636). A separate copy of the paper will be sent to the Secretary of any local society on application to the Secretary of the Corresponding Societies Committee, British Association, Burlington House.

To the Secretary of the Local Society.

SIR,—We are requested by the Corresponding Societies Committee to call your attention to a scheme drawn up by Mr. George Abbott (General Secretary of the South-Eastern Union of Scientific Societies), for promoting District Unions of Natural History Societies, a copy of which is enclosed. This scheme was discussed at the conference of delegates of the Corresponding Societies of the British Association, held at the Liverpool meeting of the Association last September, when the great advantages of federation were generally admitted, and some examples of it were explained. At a meeting of the Corresponding Societies Committee on October 29, the report of the conference of delegates was considered, and it was decided that, as the circumstances in which the local societies are placed are extremely varied, it is desirable that each society shall be asked its opinion on Mr. Abbott's scheme, and as to what kind of federation it considers to be the best. We have, therefore, to state that the Corresponding Societies Committee will be greatly obliged if your Society will be good enough to favour them with its views on the subject at any date not later than December 20, 1896.

We are, Sir, yours faithfully,

R. MELDOLA, *Chairman*,
T. V. HOLMES, *Secretary*,
Corresponding Societies Committee, British Association.

Floating Mercury on Water.

IN your review of Dr. Hertz' works you mention his investigations into the question of the flotation of thin metal plates, in connection with which I may mention that I have made mercury float on water on a somewhat similar principle. A few drops of mercury, half an ounce of water, and a pinch of some red powder, red lead, red oxide or vermillion were put into a small cylindrical bottle and shaken. A few small globules of mercury were then found floating together at the centre of the water surface. The shaking was frequently repeated until a small dish consisting of a large number of mercury globules was formed, which floated on the water and at the centre of its surface. Its diameter would be about 3/8 inch, and its depth about 1/16 inch. It did not disappear if allowed to rest, and though it must have been broken up each time that the bottle was shaken, it always reformed. I am unable to say whether the mercury was pure or not, or whether an acid, alkali, or salt had been added to the water, for this little experiment was made many years ago.

Glasgow, November 9. C. E. STROMEYER.

The Swallows.

I SAW martins, three or four stragglers at a time, hawking on our cliffs, on the 2nd, 3rd, and 7th of this month, and again a single bird in the gardens this morning.

May I suggest as to Lord Hobhouse's gatherings, that those which apparently returned were not the same birds, but new comers from the north. All our own sand-martins cleared out here in August.

By far the vastest, and I think the latest, great congregation I ever myself saw, was one October 12, at Wentworth House, Earl Fitzwilliam's Yorkshire seat. Almost every tree in the richly-wooded park was alive with their incalculable multitude. That was close upon 1850.

If, as has been recently said, temperature is the sole key to the times of migration, it seems strange that all our varieties of the swallow tribe should leave so much earlier in the south than in the north. This town being so recent, we have very few swallows or house-martins; but our swifts and sand-martins all disappeared this year in August. HENRY CECIL.

Bournemouth, November 9.

AFRICAN RINDERPEST.

WITH reference to Prof. Koch's present mission, I would venture to observe that the German Government does not deserve the praise given in your last issue. The German Government, like our own, has been guilty of gross negligence in not studying the nature of the rinderpest in 1891 and in subsequent years, when it killed off the cattle and the wild game in the British and German possessions in East and Central Africa.

Up to the time that the epidemic reached the Zambesi, much might have been done, had the nature of the disease been then understood, to limit its progress from the South, while the German possessions in South-west Africa might have been further protected had steps been taken to avert its progress at the Kalahavi.

The attention of the British Government was, as you say, called to the danger in ample time, but it is doubtful if in Germany the danger was even realised. It is now too late for either the British Colonies, the South African Republic, or the Germans in the South-west to do anything to stop the progress of a scourge of the nature of which we are ignorant. Prof. Koch has been engaged by the Cape Government to investigate the nature of the disease, and in his hands we may be sure that this will be thoroughly done. The practical result may be to prevent the disease from being carried to Europe by means of hides, &c.; but it is too late to save South Africa, where all ordinary means of transport have been paralysed.

I have just received a letter from Major Lugard, C.B., who is now at Lake Nyami, not far from the German frontier, which may be of interest to some. Writing on September 3 from his camp, near the Botletle River, he

says: "I am glad the Royal Society is likely to take up the question of the cattle plague. It is strange that the natives here insist that the crocodiles and hippopotami are dying of it. I cannot believe it true, but we came upon a dead hippopotamus; an unusual thing, since the people are such keen hunters, and its hide so valuable here. I shall, however, try and verify these reports, and let you know. The plague has now reached Sekome's town (near Lake Nyami), and will presently be in Damaraland and German South-west Africa. It ought to have been most easy to prevent its progress westwards, for there is but little communication between Nyamiland and the rest of the Protectorate, since the Kalahari Desert, with its sand and thirst, intervenes. But nothing whatever has been done. Beddoe tells me the natives are dying of eating too much 'rinderpest' beef. I do not know if this is true; all the natives eat it, and convert it into 'Biltong' for future use. I see that Mr. Long pooh-poohed the idea of imported hides bringing the disease into England. Probably tanned hides would not, but surely raw hides would bring it for certain? There is nothing more extraordinary in the course of this plague than the different classes of animals it has attacked in different localities. In East Africa, the buffalo, eland, and giraffe, I believe, suffered most. The common water-buck, all harte-beests, and zebra were, I think, exempt. The smaller sort of water-buck (*Kobus Kobe*) suffered to a great extent, but nothing like the other game. Yet Mr. Sharpe, now acting Commissioner in Nyasaland, reported that round Lake Moero, two years later, the animals that suffered most after the buffalo were zebra and lechive. Now here, on the Botletle River, they say crocodiles and hippopotami, and also, I have heard, elephants, donkeys, and dogs are affected. Animals are here said to go mad before death, and become very dangerous. I am delighted to hear the matter has been taken up, and is likely to be referred to a Committee of the Royal Society."

As Major Lugard has been in contact with the advance of the disease in East Africa in 1891–92, and is now brought face to face with it under most trying circumstances in South-west Africa, the account given of how differently it affects the various animals in different localities may be of interest; as also the impression left on his mind that, under proper care, the advance of the epidemic might have been averted had the British and German Governments a few years ago taken the step now adopted by the Cape Government, and examined the nature of the disease when it attacked their possessions in East Africa as in Nyasaland.

JOHN KIRK.

THE LEONID METEOR SHOWER, 1896.

THE expected display does not appear to have been a brilliant one. It may have offered a more attractive spectacle to American observers, for it seems to have been very probable that the richest part of the stream was encountered by the earth during daylight of the 14th in England. At stations far west an opportunity might have been afforded of witnessing a tolerably active return of the phenomenon; but of this we have not yet received definite information.

From my own observations at Bristol, and from others secured by Mr. Blakeley at Dewsbury, it appears that the shower was a very ordinary one, both on the mornings of the 14th and 15th. Mr. Blakeley watched the sky from midnight on the 13th to 4h. 15m. a.m. on the 14th, and during this long interval only recorded twelve Leonids. He says: "Meteors of all kinds were scarce, and the Leonid shower was especially disappointing, fewer of its meteors being seen than last year during a shorter watch of the sky. Twelve in a period extending over a period of $4\frac{1}{4}$ hours is a very poor result."

A dense fog obscured the stars at Bristol on the night of the 13th, and observations were not possible. On the 14th the sky cleared late at night, and the morning hours of the 15th were beautifully clear. From a position having a somewhat restricted view of the firmament, I counted nineteen meteors between 4 and 6 a.m., and of these eleven were Leonids. The display was, therefore, more active on the morning of the 15th than on that of the 14th, if we compare my figures with those obtained by Mr. Blakeley at Dewsbury. But the shower was of minor importance as regards numbers, and fell below the strength of that observed by me in 1879 and 1888, when certainly there was little reason to expect any pronounced activity.

Of the eleven Leonids observed by me on the morning of the 15th, three were pretty bright, and left streaks for about 5 seconds. The paths were as follows, and it would be interesting to hear of duplicate observations of either of these:—

Date.	G.M.T. h. m.	Mag.	From	To
Nov. 15	4 49 a.m.	1	200 + 18	208 + 16
,,	5 1 ,,	>1	203 + 20	210 + 18
,,	5 27 ,,	<1	$149\frac{1}{2}$ + 31	$149\frac{1}{2}$ + 33

I carefully pencilled the tracks of these and eight other Leonids on an 18-inch globe, and found the radiant point sharply defined at

$$150° + 22\tfrac{1}{2}°,$$

and this agrees very closely with the position determined in previous years.

Among the meteors I recorded, there were two Taurids, and two very swift flights from Gemini at about 108° + 25°.

A correspondent at South Croydon informs me that his attempted observations of the Leonids failed owing to overcast sky and rain. I fear, therefore, that reports generally from the London district will be very unfavourable.

Attempts to photograph the meteors, and to derive an accurate radiant by this means, will probably have met with little success anywhere in consequence of the poorness of the display. I believe that only during a very rich shower, will this method prove successful. Even then the limits of error will be larger than many people anticipate, as the meteor flights are not emanations from a point, but an area the actual centre of which is not defined with great precision. Still it is well the photographic method should be fully and fairly tried, as naked-eye observations are often more than 1° in error in fixing the radiant.

Since the above was written, several accounts have been received which show that the display of Leonids was pretty active in the early part of the night following November 14. One observer states that there was quite a rich shower of meteors at about 11h. 30m. Mr. Corder at Bridgwater watched the sky from 14h. to 18h. 30m. on November 14, and counted about seventy meteors. He saw eleven Leonids in the first thirty-five minutes of the period named, but the shower fell off rapidly afterwards. Mr. Corder determined the radiant at 146° + 25° on November 13, and thinks it shifted to 150° + 23° on November 14. On the nights of November 12 and 13 he saw fewer Leonids than on November 14, and there is little doubt that the maximum of the shower occurred early in the night of November 14, and before the moon had set.

W. F. DENNING.

For the observance of these meteors a watch was kept by me, commencing on the evening of the 12th, but the weather was such that only two nights were suitable for observation, namely the 12th and 14th. Arrangements had been previously made to keep a photographic record of the region about the radiant point, by fixing a

camera on the polar axis of a siderostat, and driving it by clockwork. In this way each plate could be exposed for forty minutes without any intervention on the part of the observer; but little result was obtained, in consequence, most probably, of the great amount of dew that was deposited on the lens.

Five plates exposed on the 12th, between 12h. 55m. a.m. and 4h. 8m. a.m.—Greenwich mean time—showed no trace whatever of any meteor; and eye observations made during the same interval, but with occasional breaks, were not very fruitful as regards results, only about twenty meteors in all being recorded, and not even all these Leonids. The evening of the 14th was very cloudy, but towards midnight the weather cleared, and turned out eventually very fine. Four plates were exposed consecutively between 1h. 20m. a.m. and 4h. 20m., but no trail was caught, although a few trails were observed to pass in the range of the wide-angle lens. It was found, however, impossible to keep the moisture away, although special precautions were taken on this evening to shield the lens. More strict attention was paid, however, to eye observations, and an almost continuous watch during the interval (three hours), mentioned above, was not devoid of results. In all, thirty-two meteors were seen: nineteen of these were judged as Leonids, ten as Andromedes, and two as sporadic. At 2h. 37m. a.m. a fine meteor was observed to pass a little to the north, and parallel to the belt, of Orion. Five short trails of distinct Leonids were observed near the radiant point. The most brilliant meteor of the evening, or rather of the morning, was that which appeared at 4h. 17m. a.m. Commencing in the northern part of the constellation of Hydra (about ζ Hydræ), it moved in the direction of Jupiter, passing a little to the south of Regulus, skirting i Leonis, and vanishing near ζ Ursæ Majoris. Its trail must have been quite 45° in length, being brilliant with a bright stellar nucleus. As this meteor's path was included in the region that was being photographed at the time of its appearance, it was a great surprise to find no sign of its trail on the plate. The general idea gathered from these two watches was that the Leonids were not more abundant than usual; in fact, one was surprised at the apparent dearth of these bodies. W. J. S. LOCKYER.

Almost exactly at 11 p.m., on November 12, 1896, I saw in the east a remarkable meteor. Castor and Pollux were practically in a vertical line, and the meteor appeared a short distance below Pollux, moving horizontally in a direction from right to left (south to north, as it were), at right angles to a line produced through the stars named. Curiously enough, the produced path of the meteor would lead to a position not far from the radiant point of the Leonids; but the direction of motion was centripetal, not centrifugal, as regards this radiant. The bright head of the meteor was soon extinguished, leaving behind it a very beautiful evanescent trail of tiny purple sparks. I saw no meteors coming from the radiant in Leo. C. T. WHITMELL.

Cardiff.

THE MOUTHE CAVE.

IN a recent number of *La Revue Scientifique*, an interesting account was given by M. Rivière of his anthropological work in connection with the "Mouthe Cave."

M. Rivière has done much research in this direction, and chiefly in the districts of Saint-Cyprien, Bugue, and Montignac. He has explored and studied minutely the caves of Pageyral, Combarelles, and Rey, about which he hopes to publish a volume, as the excavations are now complete. During his work he has come across some very curious finds.

Certainly the most interesting, because unique, cave yet visited by him is the "Mouthe Cave." It is situated near the hamlet of La Mouthe, in the neighbourhood of Saint-Cyprien, and was discovered by M. Rivière quite accidentally on September 2, 1894. The cave had been *emptied*, as was thought, by the owner, M. Lapeyre, forty-nine years before, and had been used as a barn for storing beetroot and potatoes during the severe winter months. The rubbish cleared out of it was thrown on the neighbouring fields; it consisted chiefly of bones, teeth, and cut flints, but the latter only could be found by M. Rivière. After a lapse of half-a-century, it is not surprising that the other remains had decayed and disappeared in the soil.

Returning to the cave later, in company with M. G. Berthoumeyrou, M. Rivière found at the furthest extremity several quaternary hearths, quite *untouched*. On removing a little of the soil, the explorers came across reindeers' teeth and pieces of bone; also a sea-shell, with a small hole, as if it had once been bored for suspension.

The work was not continued till the following year (1895), when in April, while levelling the floor, the slope formed by the hearths was slightly disturbed, and brought to light a semicircular hole, which proved to be the opening to a very narrow passage. A few days later the passage was explored by MM. E. and G. Berthoumeyrou, but not without great difficulty, it being little more than twelve inches high and twenty inches wide. The curious drawings, described later, were not seen till a distance of ninety yards had been reached.

Later, M. Rivière had a cutting made of dimensions strictly necessary for reaching the drawings more easily, and ascertaining the different epochs at which the cave was inhabited.

In the middle of July, some results of the excavations were sent to the Academy of Sciences, consisting chiefly of rubbings of a drawing of an animal resembling a bison or auroch. Three weeks later M. Rivière returned to La Mouthe, in order to commence a thorough and methodical exploration of the cave. All the earth, on being taken from the cave, was carefully sifted, so that nothing should be lost; bones, teeth, and flints were found. The work lasted a month, and was taken up in March and April of this year, and again in August and September.

The cave is at an altitude of about 200 yards, and 130 yards above the railway, which is about two miles away. It is situated at the top of a hill, the semicircular entrance being nearly eleven yards wide and a little over three yards high. The hamlet of La Mouthe is about 320 yards away, and the orientation of the cave is east-south-east. The rock is of very impure limestone, mixed with clay, and containing grains of quartz.

The following are the results at which M. Rivière has arrived concerning the age and former inhabitants of the cave, which has been inhabited by man at two distinct epochs.

(1) At the Neolithic epoch, since the upper surface is formed entirely of hearths containing cinders and coal, with bones of animals belonging to the present geological epoch, numerous pieces of coarse pottery, human bones, of which some seem to have belonged to one person, besides a good number of cut flints.

(2) At the Quaternary epoch, geologically speaking, for this upper surface rests on a fairly thick stalagmite which separates it from hearths which are much more ancient; the latter fact being proved by the fauna found by M. Rivière (Ursus spelæus, Hyæna, &c.). In this underlayer many cut flints were found, also weapons and instruments in bone. Amongst the latter may be mentioned a long fine needle, about six inches long, almost perfect; also bones engraved with figures, and teeth, bored, as if once used for amulets. No pottery, however,

or polished flints or human bones have been found in this lower layer up to the present time.

At a short distance from the entrance the Neolithic finds cease, leaving the stalagmite uncovered; but, on the other hand, the quaternary hearths persist, and they are less dark in colour, and of reddish hue, owing to clay with which they are mixed. Further on the hearths become simple layers of clay, containing quaternary fauna and worked flints. Further on still, about seventy yards from the entrance, there is a great accumulation of remains of bears, and hyænas' teeth, &c.

Owing to the excavations made under the direction of M. Rivière, it is possible to go about a length of 136 yards in the cave with perfect ease. A further distance of eighty yards may be traversed, but only by crawling, as the passage is very small.

The drawings on the sides of the cave were first noticed in April last year; they consist generally of two kinds—some simple, made on the walls and ceiling (vault) of the cave; others with certain features coloured with ochre. There is a third kind, consisting of a scratching of the rock, the scratches being covered also with ochre. The first and second represent animals only. In some cases it is difficult to make out what is represented; two, however, have been identified, one being a bison; the other the hinder limbs of which seem to represent a kind of ox, while the head (of which part is effaced) resembles a horse with a short mane. It measures no less than two yards in length from the tip of its snout to the end of its tail.

The photographs of these two drawings, which were sent to the Academy, were taken by M. Charles Durand, They were obtained by means of an illumination of 140 candles, and an exposure of four and a half hours. M. Rivière and M. Durand hope at some future time to photograph the other engravings.

HENRY NEWELL MARTIN.

HENRY NEWELL MARTIN was born on July 1, 1848, at Newry, Co. Down, Ireland. He was the eldest of a family of twelve, his father being at the time a Congregational minister, but afterwards becoming a schoolmaster. Both his parents were Irish, his father coming from South Ireland, and his mother from North Ireland. He received his early education chiefly at home; for though he went to several schools, his stay was not long at any one of them.

Having matriculated at the University of London before he was fully sixteen years of age (an exemption as to age being made in his favour), he became an apprentice to Dr. McDonagh, in the Hampstead Road, London, in the neighbourhood of University College, on the understanding that the performance of the services which might be required of him as apprentice, should not prevent his attending the teaching at the Medical School of the College, and the practice at the Hospital. It was here that I made his acquaintance in 1867. I was at that time teacher of histology and practical physiology at the School, having succeeded the late Dr. George Harley, and I well remember that Martin asked my permission to attend my course, in face of the drawback that, owing to his duties as apprentice above mentioned, he could only give to the study half the time demanded. I unwillingly gave permission; but soon found that Martin learnt in his half time more than the rest of the students in their whole time; and thus begun a friendship between us, which lasted until his death. During his career at University College he greatly distinguished himself, taking several medals and prizes. In 1870 he obtained a scholarship at Christ's College, Cambridge, Liversidge, now Professor of Chemistry in the University of Sydney, then a student at the Royal School of Mines, gaining one at the same time; he had, in the summer of that year, conducted at Cambridge a class of Histology for the late Sir G. Humphry. Though elected to the scholarship, Martin had some doubts whether he ought to take it up, and anxiously consulted me on the matter. I believe that my being able to tell him that I, too, was about to go to Cambridge, having been appointed Prælector of Physiology at Trinity College, finally removed all hesitation. Thus we two went up to Cambridge together in the October of that year. I at once asked him to assist me by acting as my demonstrator, and during the whole of his stay at Cambridge he was in every way my right hand. His energy and talents made my work much easier, and his personal qualities did much to make natural science popular in the University. At that time there was, perhaps, a tendency on the part of the undergraduate to depreciate natural and, especially, biological science, and to regard it as something not quite academical. Martin, by his bright ways won, among his fellows, sympathy for his line of study, and showed them, by entering into all their pursuits (he became, for instance, President of the Union, and Captain of the Volunteers), that the natural science student was in no respects inferior to the others.

In Cambridge, as in London, his career was distinguished. He gained the first place in the Natural Science Tripos of 1873, the second place being taken by Francis M. Balfour; at that time the position in the Tripos was determined by the aggregate of marks in all the subjects. While at Cambridge he took the B.Sc. and M.B. London, gaining in the former the scholarship in Zoology; he proceeded later to the D.Sc., being the first to take that degree in Physiology So soon as, or even before, he had taken his degree, he began to devote some time to research, though that time, owing to the necessity of his making money by teaching, was limited; his first publication was a little paper on the structure of the olfactory membrane, which appeared in the *Journal of Anatomy and Physiology*.

In the summer of 1873, I had assisted the late Prof. Huxley in the course of Elementary Biology which he initiated at the Royal College of Science, and in the following year I introduced a similar course into my teaching at Cambridge. In this Martin was my chief assistant; he also subsequently acted as assistant in the same course to Prof. Huxley. One result of this was that he prepared, under Huxley's supervision, a text-book of the course which, under their names, appeared with the title "Practical Biology," and which has since been so largely used.

In 1874 he was made Fellow of his College, and giving himself up with enthusiasm to the development of natural and, especially, of biologic science at the University, was looking forward to a scientific career in England, if not at Cambridge. About that time, however, the Johns Hopkins University at Baltimore was being established, and such was the impression made by Martin upon those with whom he came in contact, among others Dr. Gilman, of Baltimore, that in 1876 he was invited to become the first occupant of the chair of Biology which had been founded in the Johns Hopkins University. This offer he accepted, and thus nearly the whole of his scientific career was passed in America. He went out prepared to develop in his new home the higher teaching of biologic science, especially that spirit of research which alone makes teaching "high"; and during the rather less than a score of years which made up his stay at Baltimore, he produced a very marked effect on American science, fully working out the great aim of the University which had adopted him. By himself, or in concert with his pupils, he carried on many important investigations, among which may especially be mentioned those on the excised mammalian heart, one of which formed the subject of the

"Croonian Lecture" of the Royal Society in 1883. These were, in 1895, republished in a collected form by his friends and pupils in America, under the title of "Physiological Papers." And he sent out into the States a number of trained physiologists, fired with his own enthusiasm, who are continuing to advance the science, and one of whom has succeeded him at Baltimore. He also found time to write expository works, and his "Human Body," "Briefer Course" and "Elementary Course," deservedly became very popular in the States.

Upon his first appointment he had the charge of the whole subject of animal biology, and since he was himself more distinctly a physiologist, it was almost his first duty to secure or train up a colleague who should devote himself to morphology. Martin early saw the worth of one of his students, W. K. Brooks; to him he gradually entrusted morphological matters, and thus prepared not only the way for a separate chair of Zoology, but also the man to fill it.

He was elected into the Royal Society in 1885; he also received the title of Hon. M.D. from the University of Georgia.

Martin married in 1879 Mrs. Pegram, the widow of an officer in the Confederate army; but there was no issue, and in 1892 his wife died.

Even before his wife's death his health had begun to give way; and after that event, he became so increasingly unfitted for the duties which his own previous exertions had raised to a very great importance, that in 1893 he resigned his post.

After his resignation he returned to this country, for he had never become an American citizen, and was looking forward to being able, with improved health, to labour in physiological investigations, either at his old University or elsewhere in England. But it was not to be. Though he seemed at times to be improving, he had more than one severe attack of illness, and never gained sufficient strength to set really to work. During the past summer he visibly failed; and while he was striving to recover his strength by a stay in the quiet dales of Yorkshire, a sudden hæmorrhage carried him off on October 27, at Burley-in-Wharfedale, Yorkshire.

Having been for so long a stranger to this country, Martin was, personally, but little known in English scientific circles; in America, however, not in Baltimore only, but in many other parts of the States, especially among the younger physiologists, he has left behind him a memory which will not soon pass away; while those who knew the brightness of his early days in this country, will always hold him in affectionate remembrance. And it may here, perhaps, be granted to myself to say that I can never forget what he was to me in my early days at Cambridge, and the sadness which I am feeling in the thought that he now, as well as Balfour, is no more, is mixed with pride at having been a help to two such men.

M. FOSTER.

NOTES.

ADMIRAL SIR G. H. RICHARDS, whose death on Monday we regret to announce, earned the high esteem of men of science by his valuable hydrographical labours in various parts of the world. He was a scientific navigator, and during his life he contributed much important knowledge to marine surveying. The following particulars of his career are from an obituary notice in the *Times*:—Admiral Richards was born in 1820, and he entered the Navy in 1832. Three years later he was appointed as a midshipman in an expedition fitted out for a voyage of exploration and survey in the Pacific Ocean. He served for five years in the *Sulphur* during the surveys of the west coasts of South and North America, the Pacific Islands, New Guinea, and the Moluccas. As lieutenant on the *Philomel* he took part in a survey of the Falkland Isles in 1842, but circumstances arose which prevented the ship from completing the work. Later he was employed for four years surveying the coasts of New Zealand. Returning home in 1852, Commander Richards found an expedition fitting out for the Arctic regions, to continue the search for the missing ships under Sir John Franklin. He volunteered for and was immediately appointed to this service, sailing in command of the *Assistance* as second to Sir Edward Belcher in the Wellington Channel division of the expedition. While on this service he conducted several extended sledging expeditions, travelling more than 2000 miles over the frozen sea, and being absent from the ships on this duty for a period extending over seven months. Upon the return of the search party he was promoted to the rank of captain, and in 1856 he was appointed to the command of the *Plumper* for the survey of Vancouver Island and the coasts of British Columbia. He was employed for seven years in completing the surveys of Vancouver Island and the adjacent coasts, returning to England in 1863 by the islands of the Western Pacific, Australia, and Torres Straits, making surveys and carrying chronometric distances by the way. This voyage completed his third circumnavigation of the globe. On his arrival at home Captain Richards found himself appointed to the high post of Hydrographer of the Navy, and he discharged the duties of this responsible position for ten years, retiring in 1874. As was only natural, a man of the attainments and experience of Sir George Richards was welcomed and honoured by the principal scientific bodies. In 1866 he was elected a Fellow of the Royal Society, and in the same year a Corresponding Member of the Academy of Sciences of Paris. He was also a Fellow of the Royal Geographical Society. Nor did his energy permit him to relinquish active work on giving up the post of Hydrographer. After his retirement he occupied the position of managing director of the Telegraph Construction and Maintenance Company, and under his direction many thousands of miles of submarine telegraph cables were laid in various parts of the world. During his services at the Admiralty and subsequently he was a trusted adviser of several Administrations, and was a member of numerous Committees on confidential and general questions. He was also president of the Arctic Committee, which sat in 1875.

AN appeal is being made to the men of wealth in America to provide a suitable building for the societies composing the Scientific Alliance of New York. The combined membership of these societies is now over one thousand. Nearly all of them issue valuable publications; several of them possess important libraries and growing collections of specimens, and all are actively engaged in promoting original research. Burlington House partly provides for London scientific societies, but there is no building of like character in New York, though it is hoped that one will be provided by the enlightened liberality of private citizens.

THE meeting and journey to Brighton of motor-cars, arranged by the Motor-car Club as an inauguration of the appearance of those vehicles on highways under the sanction of the Act passed last Session, took place on Saturday, November 14. Fifty-four vehicles were entered for the run, but less than half of them were able to start, owing to the dense crowd of sight-seers in London and unfavourable weather. The distance to Brighton by the route followed is about fifty-five miles, over hilly country. The vehicles started at 10.30, but the crowd was so dense that they could only travel very slowly—about four miles an hour—over the first part of their course. The two Bollée cars were the first to arrive at Brighton, which they reached at 2.30 and 2.45 respectively. These did not, however, travel by way of Reigate, but went direct to Brighton, thereby saving several

miles in point of distance, and the loss of time entailed by the crowded roads into and out of Reigate. Even when this is taken into account, their rate must have been sixteen or seventeen miles an hour. The Panhard car, which won the race from Marseilles to Paris, arrived at 3.46, and Mr. H. J. Lawson's car at 4.52, after which cars arrived every few minutes. Up to six o'clock thirteen cars had pulled up at their Brighton destination, and twenty arrived there without accident out of the twenty-two which left Brixton. The Panhard car, a phaeton of the British Motor Syndicate, and the "Present Times" car raced back from Brighton to London on Tuesday. The first of these covered the distance in three hours fifteen minutes, stoppages deducted—an average speed of sixteen miles an hour. The second car came in five minutes behind, and the third half an hour later. In connection with this subject, reference may be profitably made to the current number of *Industries and Iron*, dealing almost entirely with auto-cars and their development. One of the features of the number is a reprint of the paper on "Horseless Road Locomotion," read by Mr. A. R. Sennett at the Liverpool meeting of the British Association, accompanied by the many interesting illustrations shown at the meeting.

A COMPLETE edition of the works of Descartes, edited by Prof. Ch. Adams, of Dijon, and M. P. Tannery, of the Collège de France, is to be published under the auspices of the French Ministry of Public Instruction, in honour of the third centenary of the birth of that philosopher. The edition will contain not only Descartes' philosophical and scientific publications, but also five volumes of correspondence.

DR. PERCY FRANKLAND, F.R.S., will read a paper on November 24, at the Institution of Civil Engineers, on "The Bacterial Purification of Water." In view of the controversy which has recently arisen on the bacteriological aspect of the County Council's report on the London Water Supply, the above paper should afford an appropriate opportunity for the discussion of various questions connected with water bacteriology.

THE Sunday Lecture Society has arranged a short course of twelve lectures, to be given in St. George's Hall, Langham Place, on Sunday afternoons at 4 o'clock, commencing on November 29. Among the lecturers who have been engaged are Prince Kropotkin, Mr. Robert Wallace, M.P., Prof. Miall, F.R.S., Prof. Vivian B. Lewes, Prof. Norman Collie, F.R.S., Dr. Morris, C.M.G., Dr. C. W. Kimmins, Mr. Arthur Claydon, Rev. H. N. Hutchinson, Mr. Richard Kerr, and Mr. W. Herbert-Jones.

REFERRING to the note in last week's NATURE, announcing a prize of £50 for the best treatise upon "the causes of the present obscurity and confusion in psychological and philosophical terminology, and the directions in which we may hope for efficient practical remedy," we are informed that the members of the Committee of Award to whom competing essays may be sent, are as follows:—Prof. Sully, 1 Portland Villas, East Heath Road, Hampstead, London, N.W.; G. F. Stout, University, Aberdeen, N.B.; Prof. Titchener, Cornell University, Ithaca, N.Y.; Prof. Kulpe, Wursburg, Germany. Arrangements are being made to add a French member to the Committee.

THE *British Medical Journal* states that the Russian National Health Society has finally selected November 24 (December 6) as the date for the Jenner celebration. The numerous delays and postponements which have occurred, while they have been unfortunate in some ways, have enabled the Society to gather a more representative collection of exhibits than they could have done had the celebration been held earlier. Nearly all the foreign Governments to whom application was made have sent something of interest. Quite recently a friendly expression of good will was received in reply from Lord Salisbury, who stated that he had brought the matter before the Queen, and that her Majesty had been graciously pleased to present the Society with an engraved portrait of Lady Mary Wortley Montague, whose connection with small-pox prevention is well known to every one. This gift from the Queen is highly appreciated by the Society.

THE *Times* correspondent at Buffalo reports that immediately after midnight on Sunday last, the machinery which has been erected at Niagara Falls for the production of electric power and its distribution, was set in motion; and the receipt of the power at Buffalo, twenty-six miles distant, was announced by a salute of artillery. The first Buffalo customer is the Buffalo Street Railway Company, supplying street conveyance for the entire city of 375,000 souls. This was originally worked by horses, and later by dynamos driven by local steam-engines. The latter are now superseded to the extent of 1000 horse-power out of a total of 7000 from the cataract of Niagara. The aggregate horse-power from Niagara already contracted for in Buffalo is 10,000; and many manufacturers are anxiously waiting to have their applications accepted. From this it is safe to predict that it is only a question of time, and no very great time, when all of the industries here requiring power will receive it from Niagara Falls, and that the twenty-two miles separating the two cities will be built solid with smokeless and teeming factories.

PROF. D. G. ELLIOT, the leader of the Field Columbian Museum of Chicago Expedition, and Mr. C. E. Akeby, his assistant, left Southampton on Saturday for New York by the *St. Louis* on their return from a most successful expedition into Somaliland, whither they went in March last for the purpose of making a natural history collection for the museum. In conversation with a representative of Reuter's Agency, Prof. Elliot said:—"I have obtained a very extensive collection, chiefly of the large mammals, probably the most complete ever brought out of any country by one party. No fewer than fifty-eight cases and barrels were shipped direct from Aden to Chicago, where they will arrive at the end of November. I obtained, moreover, over 300 specimens of birds, fish, insects, and reptiles."

IN an interview with a representative of Reuter's Agency, M. de Gerlache, the lieutenant in the Belgian Navy who is the organiser and leader of the projected Belgian Antarctic expedition, stated that the expedition is to start from Antwerp on or about July 15 next, in the steamer the *Belgica*, which at present is lying at Sande Fiord, in Norway. The vessel will have to undergo extensive alterations before she enters on her voyage, especially with a view to securing her against ice-pressure; and a laboratory is to be constructed on the deck for the use of the scientific members of the expedition. The *Belgica* will carry a three-years' supply of provisions, a considerable portion of the preserved food having been specially prepared for the expedition. The scientific staff will consist of M. Archowsky, a Belgian geological chemist, who is attached to the General Institute of Chemistry at Liège; M. Danco, a Belgian artillery lieutenant, to whom the magnetic and meteorological observations will be entrusted; M. Racovitza, who will conduct the dredging operations; and M. Taguin, a Belgian, who, in addition to his duties as doctor to the expedition, will assist the other scientific members in their work. The members of the expedition will devote themselves more especially to geological and zoological research. They will determine the sea temperature at different depths, and, in short, aim at making researches similar to those made by the *Challenger* and in other Antarctic expeditions.

THE Russian Geographical Society has received a very interesting piece of news from Sven Hedin, the Swedish explorer,

who now completes already his second year of travels in Central Asia. He went in December last from Kashgar to Khotan, and from this town he undertook the exploration of the part of the Gobi Desert which is known under the name of Takla Sands. There he discovered the ruins of two cities, one of which was very big, and now strikes the traveller by the purely Indian character of its ruins. Following the banks of the Keria River northwards, Sven Hedin crossed the desert, meeting on his way with a tribe, entirely isolated from all communication with the outer world; and finding full herds of the wild camel, of which he secured three specimens. Then, after an eight days' march, he reached the region where the Chinese maps place Lake Lob-nor, and which is situated to the north of the lake which was first visited by Przevalsky, and was described by him as the Lob-nor, going since on our maps under this name. Traces of an immense lacustrine basin, partly covered with woods and thickets, were discovered by Hedin in the region assigned to Lob-nor by the Chinese maps, as well as several lakes, which were filled up, nine years ago, by the waters of the Tarim River, as its bed seems to have been obstructed by sands, and it consequently began to flow northwards. We thus have two separate lacustrine basins, the Northern and the Southern Lob-nor, which are in mutual dependency, and, both being fed by the Tarim, alternately receive its waters.

SOME little time ago (August 27, p. 402) the announcement was made in these columns that Prof. J. C. Ewart had succeeded in obtaining a male hybrid between a male Burchell's zebra (*Equus Burchelli*) and a mare (*E. caballus*). A full description of the animals, with illustrations, appears in the November number of *The Veterinarian*.

REFERRING to the strange purple patches on pavements, described by Miss A. Pedder in last week's NATURE, two correspondents suggest that they are produced by the aniline colour of fragments of so-called copying-ink pencils, dropped in the process of sharpening, or broken off while the pencils were being used.

THE Annual "Cryptogamic Botanical" meeting of the Essex Field Club will be held on Saturday next, at Chingford. The objects of search will be mainly the smaller fungi and the Mycetozoa, under the direction of Mr. Arthur Lister and Dr. M. C. Cooke. Those wishing to attend should communicate with Mr. W. Cole, Buckhurst Hill, Essex.

A CIRCULAR announces to us the formation of the British Mycological Society, having for its objects the study of mycology in all its branches, systematic, morphological and pathological, the publication of annual reports recording all recent discoveries in any branch of mycology, and more especially giving a brief synopsis of the work of European mycologists and the recent additions to the British Fungus Flora. An annual week's meeting or foray will be held at some place previously determined at the annual meeting. Mr. George Massee, Royal Herbarium, Kew, has been elected first President, and Mr. Carleton Rea, 34 Foregate-street, Worcester, is the Secretary. The first meeting of the Society will be held in Sherwood Forest, commencing on the third Monday in September 1897.

LORD WALSINGHAM and his Zoological Secretary, Mr. J. H. Durrant, have published a pamphlet entitled, "Rules for Regulating Nomenclature, with a view to secure a strict application of the law of priority in entomological work." The subject of zoological nomenclature has been a vexed question for half a century, and, if we may judge from the amount of discussion that has recently occurred, we must conclude that zoologists are still far from agreement as to the best means for attaining the object they so much desire, viz. a set of cosmopolitan and permanent names for all kinds of animals. Lord Walsingham has not, we believe, hitherto expressed any formal opinion on the subject; and as he has for many years devoted great attention to one of the most extensive and difficult departments of zoology, his opinions will no doubt receive full consideration from other naturalists. The point most prominent in this pamphlet is the method of treating the names of genera. No doubt this, as well as other details, will be fully discussed elsewhere.

THE identification of the individual, with special reference to the system in use in the office of the Surgeon General of the United States Army, is the subject of a communication by Dr. C. H. Alden in the September number of *The American Anthropologist*. The method adopted consists solely of noting scars or other marks on outline diagrams representing the front and back view of a nude man. Scars form the most important group, and are arranged first as to location *L. B. head* (left back head), *R. B. head*, &c.; then according to height of subject, those upon individuals under 67 inches being placed together. Then come the tattoos, which are similarly classified according to regions, and subdivided by heights; and so on. The first classification is of course racial, whether white or coloured. The system is claimed to be specially adapted for army use, from its simplicity and facility of application. No apparatus and no camera, or elaborate personal description is required. The main object of identification is to detect deserters, and to prevent repeated enlistment. The author states that the Bertillon system requires more time than can ordinarily be given to each recruit at his examination, and there is the difficulty of the transport of apparatus. The success which has attended the use of the army system, covering a period of nearly six years, is perhaps the best proof of its value.

A DESTRUCTIVE cyclone was experienced in the Gulf of Aden on October 14, and the reports of the storm already to hand show that the disturbance is of considerable interest from a meteorological point of view. Cyclones are of very rare occurrence in the Gulf, and the storm of last month is probably the only instance of such an occurrence at this season in recent years. The disturbance was evidently travelling approximately from east to west, and must have been met with by many vessels either in the Arabian Sea or the Gulf of Aden. A discussion of the storm would be interesting, and any observations forwarded to the Royal Meteorological Society, 22 Great George Street, Westminster, will be used for tracing the development and movement of the disturbance.

THE Washington Weather Bureau has issued a pamphlet containing replies to some questions referred to the recent Meteorological Conference at Paris, and giving an account of the methods of extending meteorological observations in the interest of agriculture. By a liberal use of the telegraph and the co-operation of the Postal Service, the dissemination of weather forecasts has steadily increased until at the present time they are exhibited in more than 30,000 places. One of the simplest and most effective means of making the forecasts known consists in telegraphing them to a central point, and duplicating the messages, by using the Government franked postal cards, to all places that can be reached in useful time. A simple printing outfit, consisting of rubber logotypes with hand-stamp, is sufficient for the purpose. A novel means has also been lately tried with some degree of success, viz. the utilisation of the post-office stamp for dating the time of receipt of letters, &c., at the office of destination, by combining the weather forecast with the stamp showing the name of the receiving office, &c. Thus the recipients of the letters get the weather forecast at practically no additional cost of labour to the post-office officials. The issue of the Daily Weather Map is very speedily done by what is called the chalk-plate printing process. It consists of a steel plate, covered with specially prepared chalk, making a surface suitable

for receiving the curves and symbols representing the conditions of weather. The plate when thus prepared is stereotyped in the usual way, while the text is rapidly made up by the use of logotypes.

IN the *Atti dei Lincei*, Dr. Uberto Dutto describes an interesting series of observations performed with a D'Arsonval calorimeter on the common marmot and other animals. According to the ordinary law of dimensions, the quantity of heat radiated from the skin of an animal at a given temperature should be proportional to the square of its linear dimensions, but Dr. Dutto finds that the emission of heat is considerably greater from the marmot than from a rabbit of the same size and colour; although the temperature of the former is four or five degrees lower than that of the latter. It is suggested that these circumstances explain why the marmot and certain other mammals hybernate in winter. With the fall of temperature the vitality of the animal becomes insufficient to keep up the necessary supply of internal heat, and a period of torpor ensues.

IN a recent number of the *Johns Hopkins Hospital Bulletin* Dr. Robert Randolph gives an account of some investigations he has been carrying out on the use of absolute alcohol as a disinfectant for surgical instruments. The use of absolute alcohol as a germicide is not new. Fürbringer was the first, in a pamphlet published in 1888, to call attention to its value as a disinfectant for the hands, and Reinicke has confirmed these observations, as well as, more recently, Krönig, Ahlfeld, and Schaefer. Dr. Randolph is of opinion that although under ordinary conditions instruments may with advantage be disinfected by means of absolute alcohol, yet should pyogenic organisms be present in large numbers in any operation, this mode of sterilisation cannot with safety be resorted to.

TWO or three months ago a St. Petersburg medical review, *Vrach*, inserted a letter from a Russian doctor, M. Denisenko, who earnestly entreated his colleagues to experiment upon the sap of the Wart-wort, *Chelidonium majus*, Linn., as a possible remedy for the treatment of cancer. The sap of this plant is widely used in Russian popular medicine, as it is also in this country, for making warts disappear. Having tried for some time to use it externally against cancer-growths, M. Denisenko, came to the use of a preparation of the *Chelidonium* sap, which he rendered public, as an internal remedy. After a prolonged use in very small doses, this preparation seemed to make the cancer growths disappear. Now the same review (No. xxxiv., August 25, September 6) contains a paper, by the Russian doctor, in which the history of seven cases of cancer are given, four being cases of external growths in such places of the body as rendered surgical operations of no use, and three cases being internal-growth in the œsophagus and the stomach. The former are illustrated by photographs, from which it would seem that the effects of the above-mentioned internal treatment are simply astonishing. The growths have totally disappeared. As to the cancer-growth in the œsophagus, it has so much diminished that the patient, who formerly could swallow liquid food only, can now swallow chopped meat, bread, and hard-boiled eggs, while no more traces of a swelling are to be found in the œsophagus. This appears to be the first case on scientific record of cancer-growths having been made to disappear by the use of internal remedies only. Of course, it has to be ascertained whether the growths will not re-appear; and moreover, as the *Chelidonium* sap contains two deadly alkaloids, the chelidonine and the sangui-pyrine, it has to be seen whether its continued use, even in small doses, will not tell in the long run. It hardly need be added that, owing to the poisonous nature of the remedy, it must, in no case, be used without the prescription of a medical man. Cases of *Chelidonium* poisoning are not uncommon in popular medicine. Dr. Denisenko concludes by appealing for further experiments, in such cases where surgical operation is not possible.

THE *Kew Bulletin* for September-October records the successful growth in Queensland of a new seedling variety of the sugar-cane, derived originally from seed obtained from Barbadoes.

INTEREST in Arctic matters is so keen at the present time, that many people will probably be glad to have their attention directed to the second part of a paper on the glacial geology of Arctic Europe and its Islands, which Colonel H. W. Feilden contributes to the current *Quarterly Journal* of the Geological Society. The paper refers to proofs of changes of level in northern Norway, terrace-making in Kolguev Island, glacial geology of the Kola Peninsula, Novaya Zemlya, Franz Josef Land, and Spitzbergen. Another paper of general interest in the same number of the *Journal* is on seismic phenomena in the British Empire, by M. F. de Montessus de Ballore.

IN the third part of the first volume of the *Centralblatt für Anthropologie, Ethnologie und Ungeschichte*, in addition to the usual valuable epitome of recently published papers, there is a short original article by Prof. Aurel von Török, of Budapest, on some characteristic differences between human and animal skulls. The author looks at the skulls from above, in front, sideways and behind, and by observation, and entirely without taking measurements, he notes that the relative position of certain parts is distinctly human or characteristically animal; he gives technical names to these different conditions.

THE November Pilot Chart of the North Pacific Ocean, issued by the U.S. Hydrographic Office, contains an account of the chronological and geographical distribution of icebergs in the Southern and Antarctic Oceans, accompanied by two charts, one showing the seasonal iceberg limits, and the other the icebergs reported in the different seasons during the years 1891–5. An inspection of the charts seems to show that the bergs are formed at special parts of the Antarctic continent, and are then drifted northward and easterly, the principal groups of bergs being in the vicinity of Cape Horn, the Falkland Islands, and South of Africa, while the limits differ with the seasons. The life of a berg in the southern oceans is probably much longer than of one in the northern oceans, as they are larger and more compact, and drift to lower latitudes in the South Atlantic than those in the North Atlantic.

THE Rev. Johann G. Hagen, Director of the Observatory of Georgetown College, Washington, has rendered good service to mathematicians by preparing a complete catalogue of the works of Leonard Euler. Although several catalogues of this mathematician's works have previously been published, it was found that the information contained in these was in some respects fragmentary and incomplete in regard both to the exact titles of the papers, and to the dates of their publication. The present catalogue is divided into four sections, dealing with mathematical, physical, astronomical, and miscellaneous works respectively; and an idea of the magnitude of Euler's work may be gathered from the fact that no less than 796 memoirs and notes are included in this catalogue. The publisher is Felix L. Dames, of Berlin.

THE first issue of the *Academy*, published on October 9, 1869, contained a review of Dr. Haeckel's "Natural History of Creation," by Huxley. In the more than a quarter of a century which has elapsed since then, science has not figured very prominently in the pages of our contemporary, but it has been given a place, and Tyndall, as well as Huxley, have shone in that place. Because of this memory we have pleasure in calling attention to the entirely new issue of the *Academy*, begun by the current

number (November 14). It is proposed to widen the scope of the interests and influence of the paper; but whether the changes will mean increased attention to science, it is difficult yet to decide. At present the expansion seems to be confined to the limits of a page of science notes.

WE have received from Messrs. C. W. Faulkner and Co., the well-known artistic colour printers, some specimens of their new parlour games, together with numerous samples of their Christmas and New Year cards and calendars. In the case of the first-named, this firm has hit upon some ingenious games which combine both amusement and scientific skill, and which can be played by both the old and the young with delight. Of these we may mention the game entitled, "Attracto" or "Catch 'em," which is a novel form of fish-ponds. In place of the hook a magnet is employed, by which one must catch in a prescribed way small metal fish. "Nurky," or the game of "Ducks and Drake," also requires some skill in manipulation, and is a good round table game. Perhaps the most striking feature about the cards, in addition to their artistic nature, is the excellence of the process illustrations; the subjects being both well chosen and of a varied nature. An excellent series of new publications, both in photogravure and platinotype, in most cases well worth framing, are also issued, the types of which are both humorous and sedate. Mention must also be made of the many different styles of calendars for the coming year, for all of them are very attractive.

WE have on our table new editions of several scientific works. From Messrs. Longmans, Green, and Co. has come the third edition of Dr. Augustus D. Waller's "Introduction to Human Physiology." The principal changes in this edition are in the chapters on nerve and animal electricity, the results described in this year's Croonian lecture at the Royal Society having been incorporated. The same publishers have just issued a second edition of "The Life and Letters of George John Romanes," written and edited by his wife. To the new issue of Stanford's compendium of geography and travel, another volume by Mr. A. H. Keane has been added. The volume is on Southern and Western Asia, and like the one on Northern and Eastern Asia, published a short time ago, it forms an admirable work for reading and reference. A revised edition (the third) of "A New Course of Practical Chemistry," by Mr. John Castell-Evans, has been published by Mr. Thomas Murby. The course covers the principles of qualitative and quantitative analysis, and comprises a systematic series of experiments and problems for the laboratory and class-room. "The book is intended," says the author, "to help students to attain a real knowlege of scientific chemistry, and not to prepare for mere examinations." Certainly the student who performs all the experiments in the book, and works out all the numerical problems, will advance his knowledge considerably. So long ago as 1872, the first edition of "A Junior Course of Practical Chemistry," by Mr. Francis Jones, was published by Messrs. Macmillan and Co. It speaks much for the character of this little volume that in general arrangement, and in the prominence given to experimental work on the principles of chemistry, the course followed much the same lines as that adopted only last year by the Science and Art Department as suitable for chemical laboratory practice. The eighth edition now published will, no doubt, be widely adopted in departmental classes, and it may be introduced with advantage into all schools and colleges where elementary practical chemistry is taught.

IN the current number of the *Berichte*, Prof. Victor Meyer records some remarkable observations which he has recently made on the oxidation of hydrogen and carbon monoxide. It has been long known that these gases, even when pure, are slowly absorbed by a solution of potassium permanganate. The process has hitherto been regarded merely as one of slow oxidation, presenting no special feature of interest. But in the attempt to devise an apparatus for the exact study of the change, a remarkable fact came to light. It was found that an acidified solution of the permanganate, when continuously shaken with either hydrogen or carbon monoxide in a closed vessel, absorbed these gases, and was reduced, but that at the same time a large volume of oxygen was liberated. It was proved by a series of experiments that the evolution of oxygen in the quantity observed was in some way dependent on the oxidation process, for the permanganate solution evolved a comparatively small amount of oxygen when agitated in an indifferent gas or *in vacuo*. Without committing himself to a final opinion, Prof. Meyer can, at present, suggest no other tenable explanation of the phenomenon than that in the slow oxidation process one atom only of each molecule of oxygen yielded by the permanganate is used for oxidation, the unused halves of the molecules being set free and combining to form fresh molecules of oxygen gas. This view is in reality the same as that to which van 't Hoff has been led by the study of other less simple cases of slow oxidation.

The scheme would be as follows:— $\left.\begin{matrix} H_2 & O \\ + & \\ H_2 & O \end{matrix}\right| O = 2H_2O + O_2.$

The quantitative results, so far as they go, offer some support to this view; but a further study of the question is in progress, and the results will be awaited with great interest.

THE additions to the Zoological Society's Gardens during the past week include a Diana Monkey (*Cercopithecus diana*), a Campbell's Monkey (*Cercopithecus campbelli*) from West Africa, presented by Mrs. Skottowe; a Macaque Monkey (*Macacus cynomolgus*, ♀) from India, presented by Mrs. Monillot; a Himalayan Bear (*Ursus thibetanus*, ♂) from India, presented by Mr. Alfred W. Alcock; a Virginian Opossum (*Didelphys virginiana* from North America, presented by Mr. Edward Johnson; a Great Eagle Owl (*Bubo maximus*) European, deposited; a Green-cheeked Amazon (*Chrysotis viridigena*) from Colombia, a Malaccan Parrakeet (*Palæornis longicauda*) from Malacca, purchased; a Cocteau's Skink (*Macroscincus cocteaui*) from the Cape Verde Islands; a Gay's Frog (*Colyptocephalus gayi*) from Bolivia, received in exchange.

OUR ASTRONOMICAL COLUMN.

PARTIAL IMPACT OF CELESTIAL BODIES.—We have received from Prof. A. W. Bickerton, of the New Zealand University, a collection of papers which he has published on his theory of partial impact. This theory, he says, gives "a perfectly simple explanation of the origin of temporary, variable and double stars, and accounts for all their peculiarities. It explains the formation of multiple stars, star clusters, and also the mode of evolution of every definite form of nebula . . . ."

As for the theory itself, something may be said in its favour. The author has grasped the fact that enormous masses of incandescent matter cannot cool practically in a few weeks, and his hypothesis explains satisfactorily the phenomenon of new stars. "A typical new star is probably a thousand times as bright as our sun; it appears suddenly and disappears in a year . . . The formation of such a body is difficult enough to explain on any theory except that of impact, but to explain its disappearance is more difficult still. It is estimated that it will take the sun ten million years to lose half its lustre. Think of a sun a thousand times as bright cooling in a year. The idea is absurd." Prof. Bickerton suggested his idea of partial impact as long ago as 1879, and it certainly strengthens the hypothesis put forward by Mr. Norman Lockyer, that some stars are not stars like our sun, but masses of meteorites, which in the case of new stars and variables collide with one another.

This hypothesis was suggested in the year 1877, and in a paper read before the Royal Society on April 16, 1891, entitled

"On the causes which produce the phenomena of new stars," an historical summary of various theories is given.

THE COMPANIONS OF PROCYON AND SIRIUS.—Prof. Kreutz, telegraphing from Kiel on Sunday, has informed us that Prof. Schaeberle, of the Lick Observatory, has discovered a companion to Procyon. Its position angle was measured as 318°, the distance being 4″·6; its magnitude is 13.

A communication from Prof. Holden tells us that Clark's companion to Sirius has been also observed at the Lick by Prof. Aitken on October 24 (position angle 189°·0, distance 3″·81), October 29, and October 31, and by Prof. Schaeberle on October 29 and 31 (position angle 189°·1 and distance 3″·65). Nothing was seen of the companion at position-angle 220°, as reported by Dr. See.

"BRISBANE ASTRONOMICAL SOCIETY."—Under this title a new astronomical society has just been founded; the formation being in this wise. A 6-inch refractor, equatorially mounted, belonging to Mr. F. D. G. Stanley, Toowong, was for sale. To keep the instrument in the colony Mr. Dudley Eglinton prepared a short subscription list, and obtained sufficient contributions to purchase it. Seventy subscribers of £1 were obtained, and their subscriptions were sufficient to secure the telescope, the observatory, and "all that therein is." The purchasers then formed themselves into an astronomical society. Arrangements have been made for different sections of the society to carry out distinct branches of work, and certain evenings have been fixed when members can use the telescope. We look forward to results from this co-operative astronomical observatory.

FIG. 1.

"BULLETIN DE LA SOCIÉTÉ ASTRONOMIQUE DE FRANCE."—The November number of this journal contains three beautiful reproductions of the enlargements made by Prof. Weineck from the Lick photographs of the lunar surface. The first of these shows the crater *Tycho* and the mountainous region around it, the scale of enlargement from the original negative being about eleven times; this photograph was taken last year in October, that is about two days before the moon's last quarter. The second shows the smaller craters around *Flammarion*, while the third gives one a good view of that enormous crater *Clavius*, which has a diameter of 230 kilometres, or nearly three times that of *Tycho*. M. Gilbert gives a first contribution on mechanical proofs of the earth's rotation, dealing chiefly, in this number, with the different experiments carried out of dropping bodies from nigh elevations, and from the top of deep pits. An observer, stationed at Li-ka-wei in China, gives a brief description of the eclipse of the sun of August 9, which was unfortunately only partial there. He relates that the atmospheric conditions were excellent, which were more than they were on the island at Yéso, as our observers can testify. Photographs were taken at the most interesting stages of the phenomenon.

THE WORK OF THE SCIENTIFIC AND TECHNICAL DEPARTMENT OF THE IMPERIAL INSTITUTE.[1]

THE Scientific and Technical Department of the Imperial Institute has been recently inaugurated in order to provide for the scientific investigation of Indian and Colonial natural products, especially those which are new or little known, chiefly with a view to their utilisation in commerce, in medicine, and the arts, both within the British Empire itself, and also in foreign countries. The capacious rooms on the west corridor of the second floor have now been equipped as laboratories (Figs. 1 and 2), instrument rooms, and sample preparation rooms, to which a small reference library has been added; and a staff of skilled chemists has been appointed to assist in investigating problems relating to the utilisation of natural products of all kinds which have been referred to the Department by the Government of India, or by the Colonial Governments.

The necessary funds for the appointment of a skilled staff adequate for the commencement of operations have been contributed, with far-sighted generosity, by H.M. Commissioners of the 1851 Exhibition, who make an annual grant for the purpose; whilst the Goldsmiths' Company have made themselves responsible for the provision of the whole of the equipment of the laboratories and much of the special apparatus required. Besides this, grants are made by the Government of India towards the expenses of prosecuting Indian inquiries; whilst the Executive Council of the Imperial Institute, in addition to setting aside an annual sum from its general fund, on which there are already numerous and heavy calls (including the enormous sum of 5000*l.* per annum for Government and parochial rates and taxes), undertakes to defray expenses of a general character, both in respect of equipment and maintenance. The Imperial Government at present renders no pecuniary assistance, either directly or indirectly, to the Department. Gifts of physical and chemical instruments have been made by Dr. Ludwig Mond, F.R.S., and by Mr. George Matthey, F.R.S. The Salters' Company have rendered signal assistance to the undertaking, by founding, in association with the Department, a Research Fellowship of the value of £150, it being understood that the Salters' Company's Research Fellow shall primarily devote himself to inquiries into the chemistry of medicinal plants of Indian and Colonial origin. In another direction, too, the Salters' Company have assisted the work of the Scientific Department by endowing at St. Thomas's Hospital an additional Research Fellowship, the holder of which is expected to devote himself to inquiries into the action of drugs; so that in this way the medicinal action and remedial value of Indian and Colonial drugs, which are being chemically investigated in the Scientific Department, may be made the subject of medical study by the Salters' Research Fellow in Pharmacology at St. Thomas's Hospital. There is so much important work to be done in determining the medicinal value and precise mode of action of both old and new drugs and their constituents, that the need is already felt of further assistance in this direction.

Provision of the same kind will also be needed for conducting parallel inquiries in economic botany, particularly in the direc-

[1] Abstract of a lecture delivered at the Imperial Institute on November 9, by Prof. Wyndham R. Dunstan, F.R.S., Sec. C. S., Director of the Scientific Department; Sir Joseph Lister, Bart., President of the Royal Society, in the chair.

tion of the anatomical study and identification of economic products of vegetable origin.

It may therefore be said that there now exists, in connection with the Imperial Institute, the framework of the necessary machinery for making scientific and technical investigations of natural products of every description from all parts of the Empire. But however numerous the staff of the Department may in the future become, it is unlikely that it will ever be able to cope successfully with the enormous mass of material which present experience shows is likely to be laid before it for investigation.

There has already been formed in connection with the Department an external staff of honorary scientific and technical referees, who are high authorities on their special subjects, and who have undertaken to advise the Department on any questions which may be referred to them. The Department has been also fortunate in securing the co-operation and advice of members of the staffs of several of the most eminent public institutions in this country, and particularly of those which are furnished with appliances for undertaking special technical inquiries. Among these may be mentioned the Royal College of Science and the City Guilds Central Technical College, both of which are adjacent to the Imperial Institute at South Kensington, St. Thomas's Hospital, the Pharmaceutical Society, the Royal Indian Engineering College at Cooper's Hill, the Government Laboratories at Somerset House, at the Royal Arsenal, Woolwich, and at the Royal Mint, also the Yorkshire College at Leeds, where much valuable assistance has been rendered by the Research Laboratory of the Dyeing Department, which is endowed and maintained by the Clothworkers' Company. It is hoped that it may be possible greatly to extend this system of external referees on scientific and technical matters, and to secure the co-operation and assistance of the leading scientific and technical institutions, not only in this country but also in India and the Colonies. For while there can be no doubt that it is advantageous that the scientific examination and commercial valuation of Indian and Colonial natural products should in most cases be conducted in the metropolis, still much of the preliminary as well as some of the later operations in connection with, and arising out of these inquiries, might often be conducted in the university and technical laboratories and in the botanical gardens of our Colonies, especially if their instructions were federated with, and were working in association with the Central Scientific and Technical Department at the Imperial Institute. Such a federation, through the Imperial Institute, of scientific and technical workers in all parts of the Empire, could not fail to be an important source of strength to science, industry, and to the nation at large.

The principal work which the new department of the Imperial Institute is prepared to undertake when requested by the Indian or Colonial Governments, may be summarised as follows :—

(1) The scientific investigation of new or little-known natural products derived from India and the Colonies, with a view to their commercial utilisation throughout the Empire.

(2) The comparative examination with the same ends in view, of products of recognised value and importance, which, although known to occur and to be producible in India and the Colonies, are at present obtained commercially from other sources.

(3) Advising the Indian and Colonial Governments on all scientific questions relating to the production, manufacture, and commercial utilisation of materials occurring within the British Empire.

In order that the new organisation may be of real utility to India and the Colonies, it is necessary that their Governments, through their recognised representatives in this country, should bring themselves into close communication with the scientific department, and be the means of transmitting inquiries and suggestions from their respective Dominions as to the investigations which should be made, and also reporting to their respective Governments the result of the inquiries and the recommendations based upon them.

It may be useful to allude here to the excellent preliminary arrangements which have already been made by the Indian Government for this purpose ; for the example thus set by India will, it is hoped, be followed by at least all the more important of our colonies. The Government of India has arranged that information as to the questions demanding attention shall be obtained in Calcutta by a specially appointed officer attached to the Revenue and Agricultural Department, the Reporter on Economic Products, Dr. George Watt, C.I.E., who is in constant communication, through the India Office, with the Imperial Institute, and is charged with the collection, in India, of samples of the various products requiring investigation, and their transmission to the Imperial Institute, together with suggestions as to the points needing inquiry.

The arrangements connected with the disposal of these products are made by a special Committee appointed by the Secretary of State for India, which is presided over by Sir Steuart Bayley, K.C.S.I., and consists of Indian officials who are familiar with the needs of India, and the possibilities of promoting Indian commerce, viz. :—Sir Charles Bernard, K.C.S.I., Sir Owen Tudor Burne, K.C.S.I., Sir George Birdwood, M.D., K.C.S.I., and Sir Alexander Wilson, K.C.S.I. The experienced Curator of the Indian Section of the Imperial Institute, Mr. J. R. Royle, C.I.E., acts as secretary. To this Committee is added any official of the Government of India who may be on leave in this country, and is likely to be able to render assistance.

FIG. 2.

The Committee is charged with the maintenance and renewal of a thoroughly representative collection in the galleries of the Imperial Institute, illustrative of the chief natural products and principal manufactures of India. A similar but more extensive collection is maintained, under the supervision of Dr. Watt, at the Indian Museum at Calcutta.

The Committee receives periodical reports from the Director of the Scientific Department of the progress of investigations, and acts as the channel of transmission to India of results and recommendations.

Now that the Scientific and Technical Research Department has been organised on its experimental side, the Executive Council of the Imperial Institute have in view the perfection of preliminary arrangements that have already been made to bring the results and information obtained by this department under the immediate notice of merchants and others who control

British and foreign markets, and in this matter, too, they will look for active assistance and co-operation from all the Colonies.

No account of the organisation of the Scientific and Technical Research Department would be complete without some reference to the part which Sir Frederick Abel, the Secretary and Director of the Institute, has played in this matter. The bringing into existence and into prominence of this side of the work of the Imperial Institute, the importance of which was fully realised by its founders, is mainly due to his enthusiasm and energy, and indomitable courage in face of numerous difficulties.

The following is a brief epitome of the more important work which is at the present time occupying the attention of the Department.

The Indian Coal Supply.—Chemical analyses are being made in order to determine the value of the coal deposits occurring in different parts of India, and the results thus obtained are being supplemented by practical tests.

The Iron Ores of India.—Chemical examinations are being made of the deposits of iron ore occurring in different districts of India, and after the analytical results have been obtained the question of the best methods of smelting these ores will be investigated. The examination of a number of specimens derived from the Salem district of Madras, and composed generally of magnetite, has already been completed.

Indian and Colonial Fibres.—The chemical examination is being conducted, and practical tests are being made of the chief Indian and Colonial fibres, with a view to the cultivation of those which prove to be of commercial value. A chemical investigation is also being made of the composition of jute fibre at different stages of its growth, with the view of determining the influence of age on the composition and strength of jute fibre cultivated in India. Special experiments are in progress in reference to the possibility of chemical treatment of jute fibre in India, with a view of retarding or preventing certain changes which occur during its transport to this or other countries. In their inquiries the Department has the advantage of the advice of Mr. G. F. Cross and Mr. C. E. Collyer.

Indian Opium.—A systematic inquiry is being conducted into the methods used in the production of opium in India, with a view to improving the quality of Indian opium for medical use and for the manufacture of morphia and other valuable alkaloids. In connection with this inquiry the Government of India is causing to be collected a number of specimens of poppies, of opium, and of the bye-products and materials used in preparing it in each of the opium districts of India.

Indian and Colonial Medicinal Plants.—The chemical examination and therapeutic trial of the constituents of a number of important Indian and Colonial medicinal plants is in progress, with the object of determining which are of real medical value, and a similar examination is being made of certain well-known drugs which it would appear might be successfully cultivated in India and the Colonies.

Essential Oils and Perfumes.—A preliminary chemical examination of a number of essential oils and perfumes produced at the Government Flower Farm at Dunolly in Victoria has been completed, by M. Umney, and these are also being compared, with especial reference to their commercial value, with the best English and French oils now in commerce.

Indian Dye-stuffs.—The chemical examination of the principal Indian dye-stuffs has been undertaken in order to ascertain the nature of the chief colouring matters, and to determine which are likely to be valuable as dyes, and to ascertain the best methods or employing them. Most of this work is being carried on by Prof. Hummel and Mr. A. G. Perkins in the Clothworkers' Research Laboratory at the Yorkshire College, Leeds.

The Food Grains of India.—A systematic investigation of the constituents of Indian food grains is being conducted, their chief constituents are being ascertained, and their dietetic value determined. This inquiry includes not merely new grains, but also the effect which climate, altitude and other conditions may have upon various well-known grains which are grown in India. On these subjects the Department has secured the valuable assistance of Prof. B. H. Church, F.R.S., and of Mr. Horace Brown, F.R.S.

Indian and Colonial Tanning Materials.—A number of Indian and Colonial plants which have been proved to possess, or are likely to have, value as tanning materials, is being conducted, and information is being obtained as to the best methods of cultivating them, and the most suitable time of collecting them for use as tanning agents.

Indian and Colonial Timbers.—A large number of Indian and Colonial timbers, specially selected by the Governments, have been submitted to mechanical tests and practical trial, so that their commercial value might be accurately determined. This work has been conducted by Prof. W. C. Unwin, F.R.S., at the Central Technical College.

All that has been attempted in this lecture is to afford a general idea of the character of the principal work on which the Scientific Department is engaged, and of its commercial bearings. The technical results of the inquiries, when complete, will be communicated to the Colonies and afterwards published, whilst any results of strictly scientific interest which may be gained will be communicated to the appropriate Scientific Society. The results of many of the inquiries must necessarily be almost entirely of technical interest, but in some cases problems of considerable scientific interest are raised. The dividing line between science and practice is hard to draw in investigations of this kind, and the interests at stake will not be faithfully served if scientific, as well as immediately practical ends, are not kept in view. It often happens that the science of to-day becomes the practice of to-morrow.

From what has been said to-night, it will be evident that the operations of the Imperial Institute in its Scientific and Technical Department are such as to command sympathy and active support in this country, as well as in India and the Colonies. It is to be hoped that all possible assistance may be rendered in extending the sphere of influence of this Department, so that it ultimately may become an Imperial Bureau of Scientific and Technical Advice, having for its chief object the acquisition of exact knowledge of the natural resources of this great empire.

EXPERIMENTS ON RÖNTGEN RAYS.

The Introduction of the use of the Camera to reduce the Size of Plates.

WE have yet no means of bringing Röntgen rays to a focus, but the thought occurred to me that instead of using large plates to cover half of the body, one might photograph the shadows as seen on the fluorescent screen by means of the camera. It was evident uniformity and steadiness of illumination for a period would be necessary; these were obtained by the methods adopted under the next heading. I tried this experiment by simply placing the camera and lens in front of the fluorescent screen and focusing on the ordinary ground glass. This experiment gave a much-reduced picture in an exposure of 1 minute 50 seconds, but a very curious result was also obtained. Clearly enough I got a photograph of the screen with the pair of forceps on it reduced in the proportion of 12 to 2 in size, but all the X-rays had not been stopped by the potassium platinocyanide screen, and although the camera was four feet from the tube, a sufficient number of rays had passed through the screen to give me a picture (on the same plate) of the brass mountings and lens of the camera. On the sensitive plate, therefore, I had obtained two pictures, one due to the ordinary rays of light from the fluorescent screen, and the other due to Röntgen rays. In the former the object was reduced, the ordinary rays having been focused by the lens, and in the latter the shadow of the brass mountings and lens of the camera were enlarged owing to the divergence of the Röntgen rays. In my next attempt I covered the front of the camera with a sheet of lead, in which I had cut a hole sufficient to allow the lens to pass through. The lens prevented the Röntgen rays going through the centre, and the lead on the outside protected the remainder of the plate, so that only one picture was got, showing a reduced photograph of the hand with the bones of the fingers quite well defined. By this means I hope to reduce the time of exposure. Now, by this new method we may be able to reduce a picture of a large portion of the human body to magic-lantern slide size right away. Another thing was noticed in this experiment—the barium salt did not photograph as easily as the potassium; but it must be remembered that the barium is yellowish-green in colour, while the potassium is blue or even slightly violet.

Another important point to be gathered from the above experiments may be noted. While we have been striving to produce more Röntgen rays in the tube, it is evident we are not utilising what we have with our present fluorescent screens. I placed three ordinary screens in front of each other, one foot apart, and found that while each became luminous under the influence of Röntgen rays, a sufficient number of them were still

passing through the whole three to give a shadow of the bones of the hand on another screen. I have advantageously employed a large screen, therefore, in which the crystals are even coarser than those previously used, and the thickness very much increased. By this means I have now no difficulty in seeing many of the deep structures of the body in movement.

Different Conditions of the Tube may be utilised for Different Effects.

Lately I have been trying to follow up Prof. J. J. Thomson's suggestion about there being different kinds of X-rays, in order to discover, if possible, whether a particular set of rays might be utilised for different tissues. Whether it be a matter of difference or intensity or difference in quality (as Prof. Thomson suggests), there can be no doubt with the tube in a certain condition the bones of the hand appear jet black on the fluorescent screen, while the soft tissues are scarcely visible. On the other hand, in a different condition of the tube the soft tissues are much more prominent and the bones faint. Following up this inquiry, I made a series of experiments by way of placing metal rings near the kathode, some of them earthed and all adjustable. I am quite aware others have placed rings of metal near the kathode, and described alterations in the tube which they have attributed to different causes. The sole object in my experiments was to afford an indication of alteration in a given condition of the tube. These experiments were so far successful, but I found much the same results could be obtained by using the discharge rods of the coil. The method adopted was, first, to heat the tube by means of a Bunsen burner until I got the exact condition required. The discharge rods were approximated until they cut out the focus tube, and then one was very slightly withdrawn until the tube again became fluorescent. The slightest alteration in the vacuum afterwards was immediately indicated by sparking across the gap. It need hardly be pointed out that an arrangement like Mr. Campbell Swinton's for correcting the vacuum by means of a magnet instead of heat would be an advantage if it could be applied to the ordinary focus tube. Once having selected the particular condition required, a small Bunsen burner below the tube may be so regulated as to give the necessary heat. By these means a particular condition of the tube may be kept up for a very long period without trouble. I have had it going on constantly in some instances for half-an-hour at a time with little or no apparent change in the appearance of the shadow of the tissues, and consequently had no difficulty in focusing the fluorescent screen on the ground glass of the camera, nor in photographing the screen with shadows of objects thereon.

Action upon Tissues and Fluorescent Screens.

Actions upon the tissues of the body have been recorded from several sources, and severe loss of skin and hair as a direct result of the application of the rays has been noted. Although I worked for months, it was only within the last few weeks that, having to place my hand near the tube, between it and the fluorescent screen, for long periods and several nights in succession, evidence of a dermatitis ensued. The hand looked as if it had been sunburned, and became red and swollen; there was afterwards shedding of epidermis and loss of hair. The severer effects remained for over a fortnight.

Another curious action on the tissues was noticed while photographing a fish. The apparatus used was the old form of German tube, and an induction coil with Tesla. After half-an-hour's exposure the back of the fish was covered with patches of phosphorescence, which remained for some hours afterwards.

It is usually considered that the action of the rays upon the potassium or barium screen is of very short duration. I have several times tried to see if the luminescence remained for any length of time after the current had been turned off, but could never record anything definite in this way. For reasons which need not be here entered upon, I had been experimenting with a view of putting the fluorescent screen into a particular condition for a period of time, and some metal objects were hung over the back of the screen to serve as a shadow. It was exposed to the effects of the rays for a quarter of an hour, and afterwards set aside where it was not acted upon by the daylight. The following evening I resumed my experiments, and found an image of the metal ring which had been used the previous night. The bluish colour was different inside and outside of the ring from that part of the screen which had been protected by the metal. The screen was immediately put past and examined for four nights in succession; each time, though less distinct, I could see the image, and it did not completely disappear for a week, during which time the screen was kept in the dark.

With regard to the action upon the tissues, I think it right to point out that there are at least two other forces at work—heat and electricity—and that while the former might not have much to do with the action on the skin, the latter might. In any case, however, the above-mentioned results were obtained after, and seem to have been the direct result of exposure to the action of forces in the region of the focus tube.

JOHN MACINTYRE.

JUMPING COCOONS.

THE curious movements of jumping beans have lately attracted some attention, though to style the spasmodic jerks of the beans jumps is to court disappointment. Some "jumping cocoons," described by Dr. D. Sharp in the *Entomologist*, were however, remarkably good athletes, for they could spring out of a small vessel, such as a tumbler, in which they were placed. These cocoons were from South Africa, but in spite of their exceptional gymnastic efficiency, Dr. Sharp hardened his heart and sacrificed them upon the altar of science, in the hope of discovering something unusual that would explain the powers of jumping. The cocoons looked like a piece of oval pottery, about five millimetres long, and having a rough surface. In each of the two investigated a pupa was found; the two were similar in every respect, and they no doubt belonged to the larvæ that made the cocoons. "This little pupa," says Dr. Sharp, "is shut up in a remarkably hard thick cocoon, and it has to get out. Nature has not provided it with caustic potash for the purpose, but has endowed it with a mechanism of complex perfection to accomplish this little object. On the front of the head it has a sharp chisel edge, and with this it has to cut through the pottery; contracting itself to the utmost in the posterior part of the cocoon, and retaining itself in this position by the hooks on the mobile part of the body, it is in a condition of elastic tension in consequence of the other side of the body being so differently formed and immobile; therefore, releasing the hold of the hooks, the pupa is discharged forwards, and the chisel piece strikes the front part of the cocoon; repeating this an enormous number of times a circle may be gradually inscribed on the inside of the far end of the cocoon, which gives way when sufficiently weakened, and the insect becomes free. In both the specimens the inside of the cocoon is about half-cut through; either this is done as the result of a prolonged series of wriggles, or of shocks such as I have described. It is by no means improbable that the early part of the performance is carving the groove by wriggling, the later part knocking it off by jumping against it." The pupa is thus a most interesting one to entomologists. The order of insects to which it belongs appears to be somewhat uncertain, but Dr. Sharp thinks it will prove to be an anomalous lepidopterous insect allied to Trichoptera, and possibly somewhere near to *Adela*.

MECHANICAL CONCEPTIONS OF ELECTRICAL PHENOMENA.[1]

MATTER AND MOTION.

UNTIL the middle of the present century the reigning physical philosophy held to the existence of what were called imponderables. The phenomena of heat were explained as due to an imponderable substance called "caloric," which ordinary matter could absorb and emit. A hot body was one which had absorbed an imponderable substance. It was, therefore, no heavier than before, but it possessed ability to do work proportional to the amount absorbed. Carnot's ideal engine was described by him in terms that imply the materiality of heat. Light was another imponderable substance maintained by Sir David Brewster as long as he lived. Electricity and magnetism were imponderable fluids, which, when allied with ordinary matter, endowed the latter with their peculiar qualities.

During the fifty years, from about 1820 to 1870, a somewhat different kind of explanation of physical events grew up. The

[1] Abridged from a lecture delivered before the Franklin Institute by Prof. A. E. Dolbear.

interest that was aroused by the discoveries in all the fields of physical science—in heat, electricity, magnetism and chemistry—by Faraday, Joule, Helmholtz and others, compelled a change of conceptions; for it was noticed that each special kind of phenomena was preceded by some other definite and known kind; as, for instance, that chemical action preceded electrical currents, that mechanical or electrical activity resulted from changing magnetism, and so on. As each kind of action was believed to be due to a special force, there were invented such terms as mechanical force, electrical force, magnetic, chemical and vital forces, and these were discovered to be convertible into one another, and the "doctrine of the correlation of the physical forces" became a common expression in philosophies of all sorts. By "convertible into one another" was meant that, whenever any given force appeared, it was at the expense of some other force; thus, in a battery, chemical force was changed into electrical force; in a magnet, electrical force was changed into magnetic force, and so on. The idea here was the *transformation of forces*, and *forces* were not so clearly defined that one could have a mechanical idea of just what had happened. That part of the philosophy was no clearer than that of the imponderables which had largely dropped out of mind. The terminology represented an advance in knowledge, but was lacking in lucidity, for no one knew what a force of any kind was.

The first to discover this and to repudiate it were the physiologists, who early announced their disbelief in a vital force, and their belief that all physiological activities were of purely physical and chemical origin, and that there was no need to assume any such thing as a vital force. Then came the discovery that chemical force, or affinity, had only an adventitious existence, and that, at absolute zero, there was no such activity. The discovery of, or rather the appreciation of, what is implied by the term *absolute zero*, and especially of the nature of heat itself, as expressed in the statement that heat is a mode of motion, dismissed another of the so-called forces as being a metaphysical agency having no real existence, though standing for phenomena needing further attention and explanation—and by explanation is meant *the presentation of the mechanical antecedents for a phenomenon, in so complete a way that no supplementary or unknown factors are necessary*. The train moves because the engine pulls it; the engine pulls because the steam pushes it. There is no more necessity for assuming a steam force between the steam and the engine, than for assuming an engine force between the engine and the train. All the processes are mechanical, and have to do only with ordinary matter and its conditions, from the coal pile to the moving freight, though there are many transformations of the forms of motion and of energy between the two extremes.

During the past thirty years, there has come into common use another term, unknown in any technical sense before that time, namely, *energy*. What was once called the conservation of force is now called the conservation of energy, and we now often hear of forms of energy. Thus, heat is said to be a form of energy, and the forms of energy are convertible into one another, as the so-called forces were formerly supposed to be transformable into one another. We are asked to consider gravitative energy, heat energy, mechanical energy, chemical energy, electrical energy. When we inquire what is meant by energy, we are informed that it means ability to do work, and that work is measurable as a pressure into a distance, and is specified as foot-pounds. A mass of matter moves because energy has been spent upon it and has acquired energy equal to the work done on it, and this is believed to hold true, no matter what the kind of energy was that moved it.

What a given amount of energy will do depends only upon its *form*; that is, the kind of motion that embodies it. The energy spent upon a stone thrown into the air, giving it translatory motion, would, if spent upon a tuning-fork, make it sound, but not move from its place; while if spent upon a top, would enable the latter to stand upon its point as easily as a person stands on his two feet, and to do other surprising things, which otherwise it could not do. One can, without difficulty, form a mechanical conception of the whole series without assuming imponderables, or fluids or forces. Mechanical motion only, by pressure, has been transferred in certain directions at certain rates. Suppose now that some one should suddenly come upon a spinning-top while it was standing upon its point, and, as its motion might not be visible, should cautiously touch it. It would bound away with surprising promptness, and, if he were not instructed in the mechanical principles involved, he might fairly well draw the conclusion that it was actuated by other than simple mechanical principles, and, for that reason, it would be difficult to persuade him that there was nothing essentially different in the body that appeared and acted thus, than in a stone thrown into the air; nevertheless, that statement would be the simple truth.

All of our experience, without a single exception, enforces the proposition that no body moves in any direction, or in any way, except when some other body *in contact* with it presses upon it. The action is direct. In a letter from Newton to his friend Bentley, he says: "That one body should act upon another through empty space, without the meditation of anything else by and through which their action and pressure may be conveyed from one to another, is to me so great an absurdity that I believe no man who has in philosophical matters a competent faculty of thinking can ever fall into it."

For mathematical purposes, it has sometimes been convenient to treat a problem as if one body could act upon another without any physical meaning between them; but such conception has no degree of rationality, and I know of no one who believes in that as a fact. If this be granted, then our philosophy agrees with our experience, and every body moves because it is pushed, and the mechanical antecedent of every kind of phenomenon is to be looked for in some adjacent body possessing energy—that is, the ability to push or produce pressure.

It must not be forgotten that energy is not a simple factor, but is always a product of two factors: a mass with a velocity, a mass with a temperature, a quantity of electricity into a pressure, and so on. One may sometimes meet the statement that matter and energy are the two realities; both are spoken of as entities. It is much more philosophical to speak of matter and motion, for in the absence of motion there is no energy, and the energy varies with the amount of motion; and furthermore, to understand any manifestation of energy one must inquire what kind of motion is involved. It is now too late to stop with energy as a final factor in any phenomenon; and the *form of motion* which embodies the energy is the factor that determines *what* happens, as distinguished from how *much* happens. Here, then, are to be found the distinctions which have heretofore been called forces; here is embodied the proof that direct pressure of one body upon another is what causes the latter to move, and that the direction of movement depends on the point of application, with reference to the centre of mass.

Action at a Distance.

Let us now look at the other term in the product we call energy, namely, the substance moving, sometimes called matter or mass. It has been mentioned that the idea of a medium filling space was present with Newton, but his gravitation problem did not require that he should consider other factors than masses and distances. The law of gravitation as considered by him was: Every particle of matter attracts every other particle of matter with a stress which is proportional to the product of their masses, and inversely to the squares of the distance between them. Here we are concerned only with the statement that every particle of matter attracts every other particle of matter. Everything then that possesses gravitative attraction is matter in the sense in which that term is used in this law. If there be any other substance in the universe that is not thus subject to gravitation, then it is improper to call it matter.

We are now assured that there is something else in the universe which has no gravitative property at all, namely, the ether. It was first imagined in order to account for the phenomena of light, which was observed to take about eight minutes to come from the sun to the earth. Then Young applied the wave theory to the explanation of polarisation and other phenomena; and, in 1851, Foucault proved experimentally that the velocity of light was less in water than in air, as it should be if the wave theory be true, and this has been considered a crucial experiment which took away the last hope for the corpuscular theory and demonstrated the existence of the ether as a space-filling medium capable of transmitting light waves known to have a velocity of 186,300 miles per second. It was called the luminiferous ether, to distinguish it from other ethers which had also been imagined, such as electric ether for electric phenomena, magnetic ether for magnetic phenomena, and so on—as many ethers as there were different kinds of phenomena to be explained.

It was Faraday who put a stop to the invention of ethers, by suggesting that the so-called luminiferous ether might be the one

concerned in all the different phenomena, and who pointed out that the arrangement of iron filings about a magnet was indicative of the direction of the stresses in the ether. This suggestion did not meet the approval of the mathematical physicists of his day, for it necessitated the abandonment of the conceptions they had worked with, as well as the terminology which had been employed, and made it needful to reconstruct all their work to make it intelligible.

It has turned out that Faraday's mechanical conceptions were right. Every one now knows of Maxwell's work, which was to start with Faraday's conceptions as to magnetic phenomena, and follow them out to their logical conclusions, applying them to molecules and their reactions upon the ether. Thus he was led to conclude that light was an electro-magnetic phenomenon; that is, that the waves which constitute light and waves produced by changing magnetism were identical in their nature, were in the same medium, travelled with same velocity, were capable of refraction, and so on. Now, that all this is a matter of common knowledge to-day, it is curious to look back no further than ten years. Maxwell's conclusions were adopted by scarcely a physicist in the world. Although it was known that inductive action travelled with finite velocity in space, and that an electro-magnet would affect the space about it practically inversely as the square of the distance, and that such phenomena as are involved in telephonic induction between circuits could have no other meaning than the one assigned by Maxwell, yet nearly all the physicists failed to form the only conception of it that was possible, and waited for Hertz to devise apparatus for producing interference before they grasped it. It was even then so new, to some, that it was proclaimed to be a demonstration of the existence of the ether itself, as well as a method of producing waves short enough to enable one to notice interference phenomena. It is obvious that Hertz himself must have had the mechanics of wave motion plainly in mind, or he would not have planned such experiments. The outcome of it all is, that we now have experimental proof, as well as theoretical reason, for believing that the ether, once called luminiferous, is concerned in all electric and magnetic phenomena, and that waves set up in it by electro-magnetic actions are capable of being reflected, refracted, polarised, and twisted, the same as ordinary light waves can be, and that the same laws are applicable to both.

Phenomena of the ether are so utterly unlike the phenomena of ordinary matter that it is apparent the name matter ought not to be applied to this medium. Furthermore, it is also apparent that all attempts to describe the properties of the ether in the terms applicable to matter will be misleading. Here is a substance which, experimentally, shows itself to be illimitable, continuous, homogeneous, isotropic, non-atomic, frictionless, incompressible, incapable of transforming its own energy, gravitationless, and insensible to all nerves, compared with what is limited, discontinuous, heterogeneous, eolotropic, atomic, frictionable, compressible, capable of transforming energy, gravitative, and upon which all nerve action depends. Are not these distinctions wide enough to make one beware of thinking of them and describing their phenomena in the same terms?

Antecedents of Electrical Phenomena.

When we would give a complete explanation of the phenomena exhibited by, say, a heated body, we need to inquire as to the antecedents of the manifestation, and also its consequents. Where and how did it get its heat? Where and how did it lose it? When we know every step of those processes, we know all there is to learn about them. Let us undertake the same thing for some electrical phenomena.

First, under what circumstances do electrical phenomena arise? (1) *Mechanical*, as when two different kinds of matter are subject to friction. (2) *Thermal*, as when two substances in molecular contact are heated at the junction. (3) *Magnetic*, as when any conductor is in a changing magnetic field. (4) *Chemical*, as when a metal is being dissolved in any solution. (5) *Physiological*, as when a muscle contracts. Each of these has several varieties, and changes may be rung on combinations of them, as when mechanical and magnetic conditions interact.

If one confines his attention to the only variable factor in the energy in all these cases, and traces out in each just what happens, he will have only motions of one sort or another, at one rate or another, and there is nothing mysterious which enters into the processes.

We will turn now to how electricity manifests itself, and what it can do. It may be well to point out at the outset what has occasionally been stated, but which, in my judgment, has not received the philosophical attention it deserves, namely, that electrical phenomena are reversible, that is, any kind of a physical process which is capable of producing electricity, electricity is itself able to produce. Thus, to name a few: If mechanical motion develops electricity, electricity will produce mechanical motion; the movement of a pith ball is a simple case. If chemical action can produce it, it will produce chemical action, as in the decomposition of water and electro-plating. As heat may be its antecedent, so will it produce heat. If magnetism be an antecedent factor, magnetism may be its product. What is called induction may give rise to it in an adjacent conductor, and, likewise, induction may be its effect.

Suppose we have a series of active machines. An arc lamp, radiating light waves, gets its energy from the wire which is heated, which in turn gets its energy from the electric current, that from a dynamo, the dynamo from a steam engine, that from a furnace and the chemical actions going on in it. Let us call the chemical actions A, the furnace B, the engine C, the dynamo D, the electric lamp E, the ether waves F.

Chemical energy	Furnace.	Steam engine	Dynamo	Arc lamp	Ether waves
A	B	C	D	E	F

The product of the chemical action is molecular motion, called heat in the furnace. The product of the heat is mechanical motion in the engine. The product of the mechanical motion is electricity in the dynamo. The product of the electrical current in the lamp is light waves in the ether. Nobody hesitates an instant to speak of light waves as forms of motion, for they are described as undulations in the ether at right angles to the direction of the radiation. No one hesitates for an instant to speak of the heat as being molecular motion, nor of the motions of the engine as being mechanical; but when we come to the product of the dynamo, which we call electricity, behold, nearly every one says, not that he does not know what it is, but that no one knows! Does any one venture to say he does not know what heat is, because he cannot describe in detail just what goes on in a heated body as it might be described by one who saw with a microscope the movements of the molecules? Let us go back for a moment to the proposition stated early in the address, namely, that if any body of any magnitude moves, it is because some other body in motion and in contact with it has imparted its motion by mechanical pressure. Therefore, the ether waves at F imply continuous motions of some sort from A to F. That they are all motions of ordinary matter from A to E is obvious, because continuous matter is essential for the maintenance of the actions. At E the motions are handed over to the ether, and they are radiated away as light waves.

Rotation in Electrical Conductors.

A puzzling electrical phenomena has been what has been called its duality—states which are spoken of as positive and negative. Thus, we speak of the positive plate of a battery and the negative pole of a dynamo, and another troublesome condition to idealise has been, how it could be that, in an electric circuit, there could be as much energy at the most remote part as at the source. But, if one will take a limp rope, eight or ten feet long, tie its ends together, and then begin to twist it at any point, he will see the twist move in a right-handed spiral on the one hand, and in a left-handed spiral on the other, and each may be traced quite round the circuit; so there will be as much twist, as much motion, and as much energy in one part of the rope as in any other; and if one chooses to call the right-handed twist positive, and the left-handed twist negative, he will have the mechanical phenomenon of energy distribution and the terminology analogous to what they are in an electric circuit. So far, there is no trouble; but one can see the rope as a whole twisting, and nothing can be seen in an electric conductor. Are not the cases more dissimilar than the mechanical analogy would make them seem to be?

Are there any phenomena which imply that rotation is going on in an electrical conductor? There are. An electric arc, which is a current in the air, and is, therefore, less constrained than it is in a conductor, rotates. Especially marked is this when in front of the pole of a magnet; but the rotation may be noticed in an ordinary arc by looking at it with a stroboscopic disc, rotated so as to make the light to the eye intermittent at the rate of four or five hundred per second. A ray of plane polarised light, parallel with a wire conveying a current, has its

plane of vibration twisted to the right or left, as the current goes one way or the other through the wire, and to a degree that depends upon the distance it travels; not only that, but if the ray be sent, by reflection, back through the same field, it is twisted as much more—a phenomenon which convinces one that rotation is going on in the space through which the ray travels. If the ether through which the ray be sent were simply warped or in some static stress, the ray, after reflection, would be brought back to its original plane, which is not the case. This rotation in the ether is produced by what is going on in the wire. The ether waves called light are interpreted to imply that molecules originate them by their vibrations, and that there are as many ether waves per second as of molecular vibrations per second. In like manner, the implication is the same, that if there be rotations in the ether they must be produced by molecular rotation, and there must be as many rotations per second in the ether as there are molecular rotations that produce them. The space about a wire carrying a current is often pictured as filled with whorls indicating this motion, and one must picture to himself, not the wire as a whole rotating, but each individual molecule independently. But one is aware that the molecules of a conductor are practically in contact with each other, and that if one for any reason rotates, the next one to it would, from frictional action, cause the one it touched to rotate in the opposite direction, whereas the evidence goes to show that all rotation is in the same direction.

How can this be explained mechanically? Recall the kind of action that constitutes heat, that it is not translatory action in any degree, but vibratory, in the sense of a change of form of an elastic body, and this, too, of the atoms that make up the molecules of whatever sort. Each atom is so far independent of every other atom in the molecule that it can vibrate in this way, else it could not be heated. The greater the amplitude of vibration, the more free space to move in, and continuous contact of atoms is incompatible with the mechanics of heat. There must, therefore, be impact and freedom alternating with each other in all degrees in a heated body. If, in any way, the atoms themselves *were* made to rotate, their heat impacts not only would restrain the rotations, but the energy also of the rotation motion would increase the vibrations; that is, the heat would be correspondingly increased, which is what happens always when an electric current is in a conductor. It appears that the colder a body is the less electric resistance it has, and the indications are that at absolute zero there is no resistance; that is, impacts do not retard rotation, but it is also apparent that any current sent through a conductor at that temperature would at once heat it. This is the same as saying that an electric current could not be sent through a conductor at absolute zero.

Material Conditions of Electrical Manifestations.

So far, mechanical conceptions are in accordance with electrical phenomena, but there are several others yet to be noted. I have spoken of electrical phenomena as molecular or atomic phenomena, and there is one more in that category which is well enough known, and which is so important and suggestive, that I wonder its significance has not been seen by those who have sought to interpret electrical phenomena. I refer to the fact that electricity cannot be transmitted through a vacuum. An electric arc begins to spread out as the density of the air decreases, and presently it is extinguished. An induction spark that will jump two or three feet in air cannot be made to bridge the tenth of an inch in an ordinary vacuum. A vacuum is a perfect non-conductor of electricity. Is there more than one possible interpretation to this, namely, that electricity is fundamentally a molecular and atomic phenomenon, and in the absence of molecules cannot exist? One may say: "Electrical *action* is not hindered by a vacuum," which is true, but has quite another interpretation than the implication that electricity is an ether phenomenon. The heat of the sun in some way gets to the earth, but what takes place in the ether is not heat conduction. There is no heat in space, and no one is at liberty to say, or to think, that there can be heat in the absence of matter.

When heat has been transformed into ether waves it is no longer heat, call it by what name one will. Formerly such waves were called heat waves; no one, properly informed, does that now. In like manner, if electrical motions or conditions in matter be transferred, no matter how, it is no longer proper to speak of such transformed motions or conditions as electricity. Thus, if electrical energy be transformed into heat, no one thinks of speaking of the latter as electrical. If the electrical energy be transformed into mechanical of any sort, no one thinks of calling the latter electrical because of its antecedent. If electrical motions be transformed into ether actions of any kind, why should we continue to speak of the transformed motions or energy as being electrical? Electricity may be the antecedent, in the same sense as mechanical motion of a bullet may be the antecedent of the heat developed when the latter strikes the target; and if it be granted that a vacuum is a perfect non-conductor of electricity, then it is manifestly improper to speak of any phenomenon in the ether as an electrical phenomenon. It is from the failure to make this distinction that most of the trouble has come in thinking on this subject. Some have given all their attention to what goes on in matter, and have called that electricity; others have given their attention to what goes on in the ether, and have called that electricity, and some have considered both as being the same thing, and have been confounded.

Relation between an Electrified Body and the Ether.

Let us consider what is the relation between an electrified body and the ether about it.

When a body is electrified, the latter at the same time creates an ether stress about it, which is called an electric field. The ether stress may be considered as a warp in the distribution of the energy about the body, by the new positions given to the molecules by the process of electrification. I have already said that the evidence from other sources is that atoms, rather than molecules, in larger masses, are what affect the ether. One needs to inquire for what knowledge we have as to the constitution of matter or of atoms. There is only one hypothesis today that has any degree of probability; that is the vortex-ring theory, which describes an atom as being a vortex ring of ether, in the ether. It possesses a definite amount of energy in virtue of the motion which constitutes it, and this motion differentiates it from the surrounding ether, giving it dimensions, elasticity, momentum, and the possibility of translatory, rotary, vibratory motions and combinations of them. Without going further into this, it is sufficient, for a mechanical conception, that one should have so much in mind, as it will vastly help in forming mechanical conceptions of reactions between atoms and the ether. An exchange of energy between such an atom and the ether is not an exchange between different kinds of things, but between different-conditions of the same thing. Next, it should be remembered that all the elements are magnetic in some degree. This means that they are themselves magnets, and every magnet has a magnetic field unlimited in extent, which can almost be regarded as a part of itself. If a magnet of any size be moved, its field is moved with it, and if in any way the magnetism be increased or diminished, the field changes correspondingly.

Assume a straight bar electro-magnet in circuit, so that a current can be made intermittent, say, once a second. When the circuit is closed and the magnet is made, the field at once is formed and travels outwards at the rate of 186,000 miles per second. When the current stops, the field adjacent is destroyed. Another closure develops the field again, which, like the ether, travels outwards; and so there may be formed a series of waves in the ether, each 186,000 miles long, with an electro-magnetic antecedent. If the circuit were closed ten times a second, the waves would be 18,600 miles long; if 186,000 times a second, they would be but one mile long. If 400 million of millions times a second, they would be but the forty-thousandth of an inch long, and would then affect the eye, and we should call them light waves, but the latter would not differ from the first wave in any particular except in length. As it is proved that such electro-magnetic waves have all the characteristics of light, it follows that they must originate with electro-magnetic action, that is, in the changing magnetism of a magnetic body. This makes it needful to assume that the atoms which originate waves are magnets, as they are experimentally found to be. But how can a magnet, not subject to a varying current, change its magnetic field? The strength or density of a magnetic field depends upon the form of the magnet. When the poles are near together, the field is densest; when the magnet is bent back to a straight bar, the field is rarest or weakest, and a change in the form of the magnet from a U-form to a straight bar would result in a change of the magnetic field within its greatest limits. A few turns of wire wound about the poles of an ordinary U-magnet, and connected to an ordinary magnetic telephone, will

enable one, listening to the latter, to hear the pitch of the former loudly reproduced when the magnet is struck like a tuning-fork so as to vibrate. This shows that the field of the magnet changes at the same rate as the vibrations.

Assume that the magnet becomes smaller and smaller until it is of the dimensions of an atom, say, for an approximation, the fifty-millionth of an inch. It would still have its field; it would still be elastic and capable of vibration, but at an enormously rapid rate; but its vibration would change its field in the same way, and so there would be formed those waves in the ether, which, because they are so short that they can affect the eye, we call light. The mechanical conceptions are legitimate, because based upon experiments having ranges through nearly the whole gamut as waves in ether.

The idea implies that every atom has what may be loosely called an electro-magnetic grip upon the whole of the ether, and any change in the former brings some change in the latter.

What I would like to emphasise is, that the action in the ether is not electric action, but more properly the result of electro-magnetic action. Whatever name be given to it, and however it comes about, there is no good reason for calling any kind of an ether action electrical.

Electric action, like magnetic action, begins and ends in matter. It is subject to transformations into thermal and mechanical actions, also into ether stress—right-handed or left-handed—which, in turn, can similarly affect other matter, but with opposite polarities.

In his "Modern Views of Electricity," Prof. O. J. Lodge warns us, in a way I quite approve, that perhaps, after all, there is no such *thing* as electricity—that electrification and electric energy may be terms to be kept; but if electricity as a term be held to imply a force, a fluid, an imponderable, or a thing which could be described by some one who knew enough, then it has no degree of probability, for spinning atomic magnets seem capable of développing all the electrical phenomena we meet.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The election to the Professorship of Geology, vacant through the death of the late Prof. Green, will take place in Hilary Term, 1897. Candidates are requested to send their applications, together with such evidence of their qualifications as they may desire, to the Registrar of the University on or before February 1, 1897. The Professor is required to lecture in Geology and Palæontology in two of the three University Terms, and to take charge of the Geological and Palæontological collections belonging to the University. He is entitled to receive £400 per annum from the University chest, which sum may be augmented to not less than £700 nor more than £900 per annum, if the University revenues permit, and unless provision for the payment of a corresponding amount shall have been made from some other source. Mr. W. B. Prowse is at present acting as Deputy Professor.

Mr. W. Ramsden has been elected Sheppard Medical Fellow of Pembroke College.

The Burdett-Coutts Scholarship will not be awarded for 1896, the only candidate who presented himself having withdrawn before the close of the examination.

Prof. E. B. Poulton has recently returned to Oxford from a visit to America.

The following have been approved by Convocation as Examiners in Medicine for 1897, 1898, and 1899:—1. For the first M.B. Examination: Prof. A. Macalister (Cambridge), in Human Anatomy. 2. For the second M.B. Examination: Prof. W. MacEwen (Glasgow), in Surgery. Dr. David Berry Hart (Edin.), in Midwifery.

The Junior Scientific Club held its first meeting this term on Friday, November 6, when Mr. D. Meinertzhagen (New Coll.) gave an interesting account of "Hawks and Hawking," and Mr. W. Garstang read a paper entitled, "The Ancestry of the Vertebrata as a Physiological Problem." The Committee for the present term is composed as follows:—President: H. P. Stevens. Treasurer: A. W. Brown. Secretaries: E. H. Hunt and I. B. Billinghurst. Editors: R. A. Buddicum, A. E. Boycott, A. C. Pilkington and A. R. Wilson.

CAMBRIDGE.—An election to an Isaac Newton Studentship of 200*l.* a year for three years will be held in the Lent Term, 1897. The student is to devote himself to research in Cambridge in astronomy or physical optics. Candidates must be Cambridge B.A.s under the age of twenty-five on January 1, 1897. Applications are to be sent to the Vice-Chancellor not later than January 25.

Mr. S. F. Harmer has been appointed Chairman of Examiners for the Natural Sciences Tripos, 1897.

The Sedgwick Memorial Museum Syndicate propose that the site granted by the University near the new museums should be abandoned, and that a new site on the ground formerly belonging to Downing College, and recently acquired by the University, should be assigned instead. Some difference of opinion is likely to arise on the expediency of the proposal, which will involve the preparation of new plans and further delay.

The following awards in Natural Science were made at Trinity College on November 14: Major Scholarship (80*l.*), O. W. Richardson, Batley School; Minor Scholarship (50*l.*), G. Barger, High School, The Hague; Sizarship, R. E. Robinson, Newcastle (Staffs.) School; Exhibitions (40*l.*), H. Gaskell (Rugby), G. Savory (Harrow), and E. E. Walker (Bradford).

DR. PHILIPP LENARD has removed from Aachen, to take up a professorship of theoretical physics in the University of Heidelberg.

MR. THOMAS TICKLE, of the School of Pharmacy, has been elected to the Salters' Company Research Fellowship in Chemistry, tenable in the Research Laboratory of the Pharmaceutical Society.

WITH reference to the note on the University College, Bristol, in last week's NATURE (p. 46) we are informed that the Bristol Town Council has altogether given the College 4000*l.* The Council gave 2000*l.* towards the Engineering wing, just opened by Mr. Wolfe Barry, and has recently granted another 2000*l.* towards the capital sum of 10,000*l.* which the College authorities are trying to raise.

A RECENT law restored to the various French University centres the title of University, together with some measure of self-government; whereas since the time of Napoleon they had simply been sections of one University, and with the title of faculties. The *Times* correspondent at Paris states that arrangements have been made to celebrate the opening of term under the new system to-day by a gathering of professors and students, over which M. Faure will preside.

AT the distribution of prizes at the Barking Technical School, by the Countess of Warwick, on November 11, an address on the technical education movement was delivered by Prof. R. Meldola, F.R.S., of the Technical Instruction Committee of the Essex County Council. In the course of his remarks, the speaker deplored the line of action so generally followed throughout Essex, as well as in other counties, and which resulted in the greater part of the fund at their disposal being frittered away in small efforts at evening instruction. The main portion of the address was devoted to pointing out the true position of evening work in the scheme of technical education. It was contended that this kind of instruction, although to a certain extent useful, and even necessary, was not in itself more than an aid to true technical education, and could not, unless crowned by higher efforts, be of any use to the country at large as a means of enabling us to compete successfully with our foreign rivals in manufacturing and agricultural industries. For this reason the speaker, while admitting the good work which had been hitherto carried on at Barking, felt bound to express his regret that so much of the resources available for technical instruction had been used up in the formation of classes for cookery, ambulance, dressmaking, and other subjects, which, in his opinion, should have been subsidised from other sources, or else taught in schools. Reference was made to the recent correspondence in the papers on the state of technical education on the continent as compared with that in this country, and figures were quoted showing the relative amount of endowment of technical high schools and polytechnics in Germany and Switzerland as compared with those in England. The speaker described from personal experience, and in high terms of praise, the zeal and energy with which men engaged all day in arduous work will come to evening classes to improve their knowledge of scientific principles. He felt sure, however, that such men were sensible enough to see how hopeless it was to make headway against the expert knowledge of highly-trained and specialised students from the German schools, who devote

the best years of their youth and manhood to acquiring a competent knowledge of the science of their subject, unless they (the evening students of this country) had, as the leaders of their industries, men of an equal training to that of their competitors. The general tendency of Prof. Meldola's remarks was to encourage more concentrated effort on the part of such large urban districts as Barking, East Ham, Dagenham, and surrounding parishes, which contain a population of some 40,000 people, and he expressed the hope that the local committees would see their way to federation and joint action in the carrying on of organised day classes, as well as the evening work upon which they had hitherto concentrated their efforts. At the conclusion of the address the Countess of Warwick, in a short and forcible speech, also urged the importance of organised day work, and endorsed the wish expressed by Prof. Meldola that Barking would be in possession of such schools at no very distant period. Mr. W. Bewers, to whom the success of the Barking School is so largely due, and who is chairman of the local committee, presided at the meeting.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, November 13. — Captain Abney, President in the chair.—A paper on some experiments with Röntgen's radiation, by Prof. Threlfall and Mr. Pollock, was, in the absence of the authors, read by the Secretary.—The authors describe a form of Crookes' tube which, while it can be made by any one capable of the most elementary glass-blowing, gives a plentiful supply of Röntgen rays. The results of their experiments may be summed up as follows: (1) The Röntgen radiation does not consist in the projection of gaseous matter, or, if it does, the amount of such matter involved is extraordinarily small. (2) The Röntgen radiation does not consist in the projection of æther streams having a velocity above a couple of hundred metres per second; this is true, whether the radiation takes place in air or in benzene. (3) The properties of the æther regarded as determining the velocity of electromagnetic waves are not greatly changed (*i.e.* not at all within our experimental limits) by the Röntgen radiation; and this applies alike to the æther in air and in benzene. (4) A selenium cell composed of platinum electrodes and highly purified selenium, is affected by Röntgen radiation to an extent which is comparable with the effect produced by diffused daylight. (5) No permanent or temporary electromotive force is set up in a selenium cell by the Röntgen radiation. The authors have come to the first conclusion by exposing an exhausted tube placed in parallel with a spark-gap, so adjusted that the spark just passes over the gap rather than through the tube, to the Röntgen radiation. They find that a vacuum tube in parallel with a spark-gap is very sensitive to changes in pressure within the tube. Conclusions (2) and (3) were arrived at by using Michelson's arrangements for the interference of two beams of light. Mr. Shelford Bidwell said he had made some experiments on the effect of Röntgen rays on the resistance of selenium, but with a negative result, although he would have detected a much smaller change than that found by the authors. It might be that this difference was due to the tube, for, in his experiment, the radiation started from a platinum plate within the tube, while in the authors' arrangement the radiation starts from where the kathode rays strike the glass of the tube. Prof. Silvanus Thompson said there were a number of points with reference to the Röntgen radiation which required clearing up. For instance, the suggestion that they were vortices in the æther had not been tested. Again, Lafay says that if the rays are passed through a metal screen which is charged with electricity, then the rays can be deflected by a magnet. He (Prof. Thompson) had not been able to repeat this experiment, neither had he that of Galitzine on the polarisation of the rays by tourmaline. The statement of Prof. J. J. Thomson, that under the influence of the radiation paraffin became a conductor, had not been satisfactorily proved. As to the wave-length, while some observers obtained values about one-tenth that of the extreme violet, another had obtained a value greater than that of the extreme red. He (the speaker) did not understand the authors' device for detecting changes in the vacuum of a tube, since every one who has worked with Crookes' tubes has found that the resistance is always greater for a spark in one direction than the other, and also varies with the battery power employed. Lenard, adopting Hertz's arrangement, uses as anode a cylinder surrounding the kathode (a disc), the idea being that by using such a symmetrical arrangement the kathode radiation was more homogeneous. It might be advisable, when seeking to produce homogeneous Röntgen rays, to adopt such a symmetrical arrangement.—Mr. Bryan then read a paper, by himself and Dr. Barton, on the absorption of electrical waves along wires by a terminal bridge. The authors employ, for the generation of the oscillations, an arrangement of the same description as that used by Bjerknes, the waves being propagated along two parallel wires about 116 m. long. In order to measure the waves, they use a small electrometer with an uncharged needle. The resistances employed to form the bridge consist of pencil-marks on ground glass. Bridges of three resistances have been examined, one having, as nearly as may be, the resistance necessary, according to Heaviside's theory, to give complete extinction of the reflected wave, and, of the others, one was of higher, and the other of lower resistance. In each case the results confirm the theory, and it is thus experimentally proved that by using a bridge of this description the reflected train of waves can be completely extinguished. Mr. Blakesley asked if the authors had made any allowance for the capacity of the wires. Mr. Campbell asked if the resistances given were expressed in ohms or in electro-magnetic units. Mr. Bodwell asked if the authors had found that the pencil-trace resistances obeyed Ohm's law. He had found that if you balanced with one cell in the battery circuit, then, on increasing the battery power to two cells, the resistance altered. Mr. Appleyard suggested that the variation was caused by the contacts at the ends not being good. Mr. Campbell said the same variation occurred in the case of mixtures of clay and plumbago, where the contacts were quite good. Mr. Carter suggested electroplating the ends to give good contact. Mr. Bryan, in his reply, said that they had not considered the question of capacity, and that, in their case, they did not require to know the resistance very accurately.

Entomological Society, November 4.—Prof. Raphael Meldola, F.R.S., President, in the chair.—Mr. McLachlan exhibited a collection of the cast nymph-skins of more than one-third of the species of European dragon-flies from the Département de l'Indre, France, sent to him by M. René Martin. Two or three of the species had been reared in an aquarium, but the identification of most of them had been secured by finding the imago drying its wings in the immediate vicinity of the cast skin.—Mr. R. Adkin exhibited a long series of *Acidalia marginepunctata* taken on the sea-coast at Eastbourne, Sussex, during the past eight summers.—Mr. Horace St. John Donisthorpe exhibited a female specimen of *Dytiscus circumcinctus*, Ahr., with elytra resembling in form those of the male. He said the specimen had been taken in Wicken Fen in August last.—Mr. Tutt exhibited a specimen of *Mellinia ocellaris* recently taken near Southend, together with a specimen of *M. gilvago* for comparison; also four specimens of *Argyresthia atmoriella* taken by Mr. Atmore last June at Lynn, Norfolk. Mr. Tutt also exhibited a long series of a *Melampias* which he had captured at Le Lautaret in the Dauphiné Alps, at an elevation of 7000-8000 feet. He observed that the specimens exhibited were peculiar in some very important particulars, combining some of the characteristics of *Erebia* (*Melampias*) *melampus*, and *M. pharte*. He said his attention had been first drawn to this form by some fine examples captured by Dr. Chapman and himself on Mont de la Saxe in 1895. Compared with the Tyrolean examples of *M. melampus*, this form showed a tendency to a lengthening of the forewings and to an obsolescence of the black dots, thus approaching *M. pharte*, but the females presented none of the typical characters of the female of *M. pharte*. On the whole, he felt satisfied that the Mont de la Saxe specimens were a form of *M. melampus*. Mr. Elwes observed that though all the continental butterflies had been so long studied by European entomologists, he did not think the form exhibited by Mr. Tutt had been hitherto noticed.—Mr. E. Ernest Green exhibited a typical specimen of *Ephyra omicronaria*, together with what he believed to be a remarkable melanic variety of the same species, taken by Dr. Dudley Wright at Pegwell Bay, near Ramsgate, in September last. Some of the Fellows present, after an examination of the specimen, expressed an opinion that it was a variety of an Acidalia, and not of *Ephyra omicronaria*.

Anthropological Institute, November 10.—Mr. E. W. Brabrook, President, in the chair.—Mr. P. L. Sclater exhibited a draught-board from Nyasaland; Mr. C. H. Read, a dance-mask

and a curious carving from the north-west coast of America; and Mr. Thompson, some small terra-cotta heads from ancient Mexico.—Mr. Henry Balfour exhibited various native Indian preparations of hemp for consumption, and an ancient bow of Assyrian type found in Egypt in a tomb of the XXVIth Dynasty, on which he read a paper. The interesting point about the bow was that it was of the composite type, at least one of the ingredients of which was not to be found in Egypt. The evidence available pointed to a more northern region, probably Assyria, as its place of origin, and this supposition was also borne our by historical facts. The indigenous Egyptian bow, a specimen of which was originally found near the other, and was now exhibited with it, was fundamentally different, being plain and not composite; the arrows also differed absolutely. A somewhat similar bow was now in the Berlin Museum. Mr. Balfour also exhibited a screen of typical Asiatic composite bows, and some transparencies in the form of thin sections cut from a number of bows of the same kind. Mr. Balfour subsequently read a paper on the life-history of an Aghori Fakir, illustrated by an extensive exhibition of drinking-cups made from human skulls. At the conclusion of the paper Dr. Leitner made some interesting remarks on the Aghori sect.

MANCHESTER.

Literary and Philosophical Society, November 3.—On methods of determining the dryness of saturated steam, and the condition of steam gas, by Prof. Osborne Reynolds, F.R.S. In certain recent attempts to ascertain the proportion of steam and water in the fluid which enters a steam engine, by means of what is called the wire-drawing calorimeter, the published results show that there remains from 0 to 5 per cent. by weight of water in the steam, after it has been drained by gravitation, in the same manner as the steam on which Regnault's experiments were made. This has necessarily excited great interest in steam engineering, and is naturally welcome, as it apparently brings the performance of the engines by so much nearer perfection. Although the results of these recent experiments appear to show the condition of dry saturated steam to be other than that on which Regnault's experiments were made, and from which the present steam tables have been calculated, still these tables have been used in deducing the percentage of water latent in the steam. Whereas, if the latent water exists, it must have existed in the steam used by Regnault, and the steam tables must also be subject to identical corrections; and, consequently, the percentage of theoretical performance of steam engines would be unchanged. It is then pointed out that, in the reduction of such of these results as have been published, use has been made of Regnault's determination of the specific heat at constant pressure of steam gas (0·48) in a manner which is not consistent with the theory of thermodynamics. Thus, in Rankine's notation, S_1 is the weight of steam per pound of fluid, and H_1 the total heat per pound from 0° C. to $T_1°$, h_1 the heat required to raise water per pound, and H_2, h_2, T_2, the corresponding values for saturated steam at the pressure after wire-drawing, and $T_2°$ the observed temperature after wire-drawing. The notation assumed for the equation of heat, neglecting incidental losses, is

$$S_1(H_1 - h_1) + h_1 = H_2 + 0{\cdot}48\,(T_2° - T_2°) \quad . \quad . \quad . \quad (1)$$

Whereas, it has been proved by Rankine that the thermodynamic expression for the total heat in superheated steam at $T_2°$ C., provided it has reached the condition of steam gas, to which the 0·48 only applies, is

$$C_1 + 0{\cdot}48\,(T_2° - T_c°)$$

C_1, being a constant, depends only on the temperature of the water, ($T_c°$) from which the steam is produced, the value of which from 0° C. is 606·7, approximately, as deduced by Rankine. Using Regnault's formula for H_2, the right member of equation (1) becomes

$$606{\cdot}5 + {\cdot}305\ T_2° + 0{\cdot}48\ (T_2° - T_2°)$$

while the value by the thermodynamic formula is

$$606{\cdot}7 + 0{\cdot}48\ T_2°$$

which gives us the excess of heat over that assumed

$$\cdot 2 + 0{\cdot}175\ T_2°$$

This excess, if T_2 were 100° C., is 17·7 thermal units, and if the initial steam pressure were 200 lbs. above the atmosphere, the latent heat being 467·5 thermal units, the percentage of water it would evaporate, at boiling point, is

$$\frac{177}{4675} = 3{\cdot}8 \text{ per cent.}$$

which is about as much as needs to be accounted for. It is also shown that, in order to render Rankine's formula applicable to wire-drawing experiments, it is necessary that the wire-drawing should be continued till the steam is gaseous, whence arises the difficulty of securing that this state has been reached. This, however, may be secured by lowering the pressure gradually after wire-drawing, and so increasing the extent of wire-drawing while observing the temperature ($T_2°$), which, after falling, will gradually become constant as the wire-drawing increases, and, when constant, will be a definite indication of this gaseous state. The necessary conditions to ensuring accuracy are then considered, and, in conclusion, it is stated that a research to verify these conclusions has been commenced by Mr. J. H. Grindley, in the Engineering Laboratory of Owens College, Manchester.

PARIS.

Academy of Sciences, November 9.—M. A. Cornu in the chair.—On the composition of the fruits of *Phœnix melanocarpa*, by M. Aimé Girard. The average weight of the fruit was nearly 8 gr., 80 per cent. of which was edible. The analysis of the latter part showed that about one-half was soluble, the chief constituent being levulose (39 per cent.); no other sugar could be detected.—On the mode of formation of the sedimentary deposits of phosphate of lime, by M. A. Carnot. From an experimental study of the ratio of fluorine to phosphorus in phosphates of various origin, and from the artificial production of such apatites by the action of solutions of fluorides upon bone, the conclusion is drawn that phosphatic deposits are of animal origin, the alkaline liquid resulting from the putrefaction of organic remains having the property of dissolving calcium phosphate to a small extent, and depositing it again upon organic substances in a manner analogous to the petrifaction of wood. The fluorine must be supplied by the sea-water. Since fluorine had not been proved with certainty to exist in sea-water, a careful examination was made, and fluorine found in sea-water in amount corresponding to 1·69 gr. per cubic metre.—On a method of steering aërostats, by M. L. Baudey.—On the distribution of motion in a homogeneous medium, and the formation of cyclones, by M. E. Leclère.—On the production of floods in the basin of the Seine, by M. H. Tarry.—Observations on the new Perrine comet (November 2, 1896), made at the Paris Observatory, by M. G. Bigourdan.—Occultation of the Pleiades, of October 23, 1896 (Lyons Observatory), by M. Ch. André.—Observations on the sun, made at the Lyons Observatory, during the third quarter of 1896, by M. J. Guillaume.—On a geometry of ruled space, by M. René de Saussure.—Linear forms of the divisors of $x^2 \pm A$, by M. P. Pépin.—On the resistance of bridges under the passage of periodic loads, especially of those provided against in the regulation of August 29, 1891, by M. Marcellin Duplaix.—On the compressibility of some gases at 0° C., and near atmospheric pressure, by M. A. Leduc. With a view of determining the molecular volumes of gases at 0° at corresponding pressures, a pressure of 1/76th of the critical pressure was chosen, so that the values fell between 35 and 113 centimetres of mercury. By means of a modified Regnault apparatus, the variations from Boyle's law were measured in the cases of carbon dioxide, nitrous oxide, hydrogen chloride, ammonia, and sulphur dioxide.—A method of studying the expansion of liquids by means of photography, by M. Alphonse Berget. Two balances of equal sensibility, with their planes of oscillation at right angles, carry two weight thermometers, one containing the liquid under examination, and the other mercury. A ray of light is reflected from two mirrors, one on each beam, and this records on a sensitive plate a curve analogous to Lissajou's figures. This curve is the graphical representation of the expansion of the liquid.—On some abnormal cases of solubility, by M. Le Chatelier.—Action of aluminium chloride upon camphoric anhydride, by M. G. Blanc. By carrying out the reaction in presence of an inert solvent, such as chloroform, a new acid $C_9H_{14}O_3$ is obtained, the salts, ethers, and chloride of which are described.—On essence of roses, by MM. Eug. Charabot and G. Chiris. This essence appears to contain minute quantities of an ether, to the presence of which in French essences the latter probably owe their more fragrant odour.—On a new ferment in the blood, by M. Hanriet. Under the name of lipase, a new ferment of blood serum is described, which is characterised by its power of saponifying fatty ethers. This ferment is destroyed by heating to 90° C.—On a chemical method of valuing commercial wheaten flours, by M. E. Fleurent. The gluten is shown to consist of two substances, to which the

names gliadine and glutenine are given. The baking value is shown to depend upon the ratio in which these two are present in the flour.—On the origin of the beetroot disease, by M. Paul Vuillemin. It is shown that the parasite named *Entyloma leproidcum* by M. Trabat, and *Œdomyces leproides* by M. Saccardo, is not a new species, but is identical with the *Cladochytrium pulposum* of Fischer.—New observations on scab in potatoes, by M. E. Roze.—On the mode of formation of zeolites, by M. A. Lacroix. In the Pyrenees, zeolites are found in considerable quantity which have been formed by the action of nearly pure water, at temperatures near 0° C., upon basic felspathic rocks.—The application of Röntgen rays to Palæontology, by M. Lemoine.—On the apparent density of clays deposited from water, by M. J. Thoulet.—On the return of some exceptional meteorological phenomena in November 1896, by M. Chapel.—On the destruction of *Heterodera schachtii*, and other animals prejudicial to the culture of the beet-root, by M. Willot.

NEW SOUTH WALES.

Linnean Society, September 30.—The President, Mr. Henry Deane, in the chair.—The Sooty-Mould (*Capnodium citricolum*, n.sp.) of Citrus trees: a study in polymorphism, by D. McAlpine. The species so far as known is peculiar to Australia. It has a remarkable life-history, and well illustrates the phenomenon of polymorphism.—Australian Lampreys, by J. Douglas Ogilby.—On the botany of the Rylestone and Goulburn River Districts, N.S.W., by R. T. Baker.—Note on *Cyprœa angustata*, Gray, var. *subcarnea*, Ancey, by C. E. Beddome.—Mr. Edgar R. Waite contributed a note on the range of the Platypus. The northern habitat is extended to 16° 45′ S. and localities quoted on the Gulf of Carpentaria 140° 56′ E., the most north-westerly point hitherto recorded.—Mr. T. Whitelegge exhibited a rare and curious Isopod, *Amphoroidea australiensis*, originally described from N.S. Wales by Dana in 1852, since when it appears to have escaped notice. The specimen exhibited was obtained on seaweed at Maroubra Bay last June; when alive it was bright olive-green, and of a similar tint to the seaweed to which it was adhering.—Prof. David contributed the following note on a remarkable radiolarian rock from Tamworth, N.S.W.:—"On September 10, in company with Mr. D. S. Porter, I observed the occurrence of a remarkable radiolarian rock on the Tamworth Temporary Common. Of this rock a hand specimen and section prepared for the microscope are now exhibited. The section is an opaque one prepared by cementing a slice of the rock about one-tenth of an inch thick on to an ordinary glass slip with Canada balsam and then etching its upper surface with dilute hydrochloric acid. The rock being partially calcareous, probably an old radiolarian ooze, the lime filling in the delicately latticed shells and interstices between the spines of the radiolaria is dissolved out, and the siliceous shells of the radiolaria become exposed to view. Some of them are exquisitely preserved for palæozoic radiolaria. The rock of which they constitute by far the larger proportion weathers into a brown pulverulent friable material like bath brick. The unweathered portions are dark bluish-grey and compact. The radiolaria appear to be chiefly referable to the porulose division of the Legion *Spumellaria*. This discovery confirms the previous determinations by me of radiolarian casts in the rocks of the New England district, and of the Jenolan Caves, N.S. Wales. The geological age of the formation in which this rock occurs is probably either Devonian or Lower Carboniferous, as *Lepidodendron australe* appears to occur on a horizon not far removed from that of this radiolarian rock. The Moor Creek limestone, near Tamworth, I find also contains numerous radiolaria."

SIR JOSEPH BANKS'S JOURNAL.

Journal of the Right Hon. Sir Joseph Banks, Bart., K.B., P.R.S., during Captain Cook's First Voyage in H.M.S. "Endeavour" in 1768–71 to Terra del Fuego, Otahite, New Zealand, Australia, the Dutch East Indies, &c. Edited by Sir Joseph D. Hooker. Pp. li + 466. (London: Macmillan and Co., Ltd., 1896.)

THIS journal, which now sees the light after varying vicissitudes, will take fitting place on our bookshelves by the side of Darwin's "Voyage of the *Beagle*" and Moseley's "*Challenger* Notes" as one of the classics of scientific travel. Sir Joseph Hooker, in realising a hope he has indulged, as he tells us, since he was a boy, adds another to the many services he has rendered to science by presenting to us this journal in the delightful form it has assumed under his editing. In an interesting preface to the volume he states the aims with which he has undertaken the task he has just completed, and from this, as well as from the charming biographical notice with which the journal is introduced, we do not scruple to quote in noticing with gratitude the appearance of this book.

"My principal motive," he says, "for editing the journal kept by Sir Joseph Banks during Lieut. Cook's first voyage round the world is to give prominence to his indefatigable labours as an accomplished observer and ardent collector during the whole period occupied by that expedition, and thus to present him as the pioneer of those naturalist voyagers of later years, of whom Darwin is the great example. This appears to me to be the more desirable, because in no biographical notice of Banks are his labours and studies as a working naturalist adequately set forth." . . . "In respect of Cook's first voyage, this is in a measure due to the course pursued by Dr. Hawkesworth in publishing the account of the expedition, when Banks, with singular disinterestedness, placed his journal in that editor's hands, with permission to make what use of it he thought proper. The result was that Hawkesworth selected only such portions as would interest the general public, incorporating them with Cook's journal, often without allusion to their author, and not unfrequently introducing into them reflections of his own as being those of Cook or of Banks. Another motive for editing Banks's journal is to emphasise the important service which its author rendered to the expedition. It needs no reading between the lines of the great navigator's journal, to discover his estimation of the ability of his companion, of the value of his researches, and of the importance of his active co-operation on many occasions. It was Banks who rapidly mastered the language of the Otahitans, and became the interpreter of the party, and who was the investigator of the customs, habits, &c., of these and of the natives of New Zealand. It was often through his activity that the commissariat was supplied with food. He was on various occasions the thief-taker, especially in the case of his hazardous expedition for the recovery of the stolen quadrant, upon the use of which, in observing the transit of Venus across the sun's disc, the success of the expedition so greatly depended. And, above all, it is to Banks's forethought, and at his own risk, that an Otahitan man and boy were taken on board, through whom Banks directed, when in New Zealand, those inquiries into the customs of the inhabitants, which are the foundation of our knowledge of that interesting people. And when it is considered that the information obtained was at comparatively few points, and those on the coast only, the fulness and accuracy of the description of the New Zealanders, even as viewed in the light of modern knowledge, are very remarkable. Nor should it be forgotten that it was to the drawings made by the artists whom Banks took in his suite that the public is indebted for the magnificent series of plates that adorn Hawkesworth's account of the voyage. Still another motive is, that Banks's journal gives a life-like portrait of a naturalist's daily occupation at sea and ashore nearly one hundred and thirty years ago; and thus supplements the history of a voyage which, for extent and importance of geographic and hydrographic results, was unique, and 'to the English nation the most momentous voyage of discovery that has ever taken place' (Wharton's 'Cook,' Preface), and which has, moreover, directly led to the prosperity of the empire; for it was owing to the reports of Cook and Banks, and, it is believed, to the representation of the latter on the advantages of Botany Bay as a site for a settlement, that Australia was first colonised."

The question that every one will no doubt ask himself is, how does it come about that a journal of so much interest, written in 1769–71, the author of which survived until 1820, occupying for no less a period than forty years the premier position in the scientific world in Great Britain, is only published now—a century and a quarter after the events which it relates. On this point the editor leaves us in no doubt, and the story as he tells it is an interesting bit of history, not without a touch of romance, and withal with features not altogether creditable to some of those concerned in it.

Although only returned from the first voyage in 1771, Banks accepted an invitation to join, as naturalist, Cook's second voyage, preparations for which began in 1772. This proposal called forth a strong protest from Linnæus, prophetic as things turned out of the fate awaiting the results of the first voyage. In a letter to Mr. Ellis, he says: "Whilst the whole botanical world, like myself, has been looking for the most transcendent benefits to our science, from the unrivalled exertions of your countrymen, all their matchless and truly astonishing collection, such as has never been seen before nor may ever be seen again, is to be put aside untouched, to be thrust into some corner, to become perhaps the prey of insects and of destruction." Banks eventually abandoned the intention to join the expedition, but nevertheless to it must be ascribed in the first instance the withholding from the public of his journal. Writing in 1782, Banks says: "The reason I have not published the account of my travels is that the first from want of time necessarily brought on by the many preparations for my second voyage was entrusted to Dr. Hawkesworth, and since that I have been engaged in a botanical work, which I hope soon to publish, as I have near 700 folio plates prepared; it is to give an account of all such new plants discovered in my voyage round the world, somewhat above 800." It is indeed remarkable that in course of his long life Banks did not give to the public his story of travel, but neither it nor yet the botanical work to which he refers in the above extract appeared. The death of his librarian and companion, Dr. Solander, is usually supposed to have led to the suppression of his botanical work—that for the fate of which Linnæus was so much concerned. One cannot help thinking when one regards the whole amount of the published writings of Sir

Joseph Banks, surprisingly little, as his editor points out, that whilst he was energetic in his correspondence and methodical in his records of the scientific observations he made, and always ready to help others in their work, he himself must have had a dislike to printer's proofs and preparing his papers for the press. To whatever cause we ascribe his action or inaction (and whether we shall ever know the real inwardness of the matter, seems now doubtful, owing to the dispersion of so much of his correspondence), the fact remains that "five folio books of neat manuscript, and the coppers of about 700 plates of plants rest in the hands of the British Museum Trustees"—the botanical results of the voyage of the *Endeavour*; a monument of energetic labour, skill, and knowledge, and all lost to science. The journal is at last before us.

With the death of Banks no better fate immediately awaited his journal. Robert Brown, unable to write the life of Banks as he intended, had the materials for this, including the journal, transferred to Mr. Dawson Turner, maternal grandfather of Sir Joseph Hooker, who caused a transcription to be made of the journal, but did not bring out the life. Subsequently, the task of writing the life not having been accomplished, the papers reached the British Museum, whence, however, they were claimed by the Peer, the representative of the Hugessen family, to which Banks's wife belonged, fortunately, however, not before the Dawson Turner transcript of the journal had been lodged in the Botanical Department of the Natural History Museum at South Kensington. A haggling over a price for the documents appears to have ensued between the British Museum and the Peer possessor, and in the result the whole collection of papers was sold off by auction in London, bringing in the sum of £182 19*s*.! *Noblesse oblige!* Well may Mr. Carruthers, in a letter to the editor, speak of this story as a distressing one. Sir Joseph Hooker has been able to trace the original document of the journal to Australia; but had the publication depended upon this, we should still have been in ignorance of the merits of Banks's work. Fortunately there was the transcript left in this country, which has enabled the editor to bring out the welcome volume before us. If the barque of Banks's reputation has suffered on the rocks of neglect or ignorance in the past, it is fortunate that so distinguished a pilot as the present editor—heir likewise as he was to a portion of the equipment prepared by Banks for the second voyage (p. 27, note)—has taken it in hand, placing it beyond further danger. The appearance of the journal will undoubtedly achieve the primary aims of the editor in his self-appointed task.

As a narrative the journal is full of charm. It comes before us, old as it is, with all the freshness of first impression. Familiar as much of what is told has now become through the writings of later travellers and modern facilities for globe-trotting, there is an unstrained interest attaching to scenes depicted by one who, almost in touch with the present generation, yet is able to describe Cape Town while it was still a Dutch settlement, and Mauritius was as yet the Isle of France, who sailed round New Zealand and determined it to be an island, and who tells us of people and places before all-levelling civilisation had removed the landmarks of natural evolution. The journal throughout abounds in evidences of Banks's keenness of observation and ardent devotion to scientific investigation; and whilst the bulk of it is descriptive, there are not wanting shrewd reflections and comments to show that problems of distribution and adaptation, the discussion of which gives zest to so many of the modern books of scientific travel, engaged the mind of the last-century naturalist. It is not necessary for the purpose of this notice, and it would take us too far, were we to follow with comments the narrative of the expedition; suffice it that we say the guarantee implied in the names of author and editor is not belied.

Of the adjuncts to the journal in its present guise—we have already spoken in praise of the narrative of Banks's life by the editor—there is also to be commended an admirable life of Dr. Solander, contributed by Mr. Daydon Jackson; and a series of notices of early voyagers and naturalists, compiled by Mr. Reginald Hooker, is a useful guide. Finally, excellent reproductions by photography of the portraits of Banks and Solander in the collections of the Royal and Linnean Societies, respectively, help to give attractiveness to this most delightful book of voyage.

THREE NEW BOOKS ON HISTOLOGY.

Handbuch der Gewebelehre der Menschen. Von A. Koelliker. 6te Auflage, Erster Band, pp. 409, 1889; Zweiter Band, Erste Hälfte, pp. 372, 1893; Zweiter Band, Zweite Hälfte, pp. 400, 1896. (Leipzig: Engelmann.)

Lehrbuch der Histologie der Menschen, einschliesslich der mikroskopischen Technik. Von A. Böhm und M. von Davidoff. Pp. 404. (Wiesbaden: J. Bergmann, 1895.

Lehrbuch der vergleichenden mikroskopischen Anatomie der Wirbelthiere. Von Albert Oppel. Erster Theil, Der Magen. Pp. 543. (Jena: Fischer, 1896.)

TO place the classical treatise of the famous Würzburg professor in a list of new books on histology, must at once strike all readers who have any acquaintance with that science as manifestly absurd. Is not this the book from whose stores of knowledge our predecessors in the teaching of the subject drew so largely, and which has served ever since as the foundation upon which modern histology has been built? Is not this the book, the translation of which by Busk and Huxley, under the auspices of the Sydenham Society, rendered the names both of its author and of its translators familiar to a long past generation of students?

Whilst to these interrogatories an affirmative answer must be given, none the less is it true that the book before us is to all intents and purposes a *new* book, giving us a presentation of the most recent advances in histology, either based upon or confirmed by the careful personal work of its author, whilst still being founded upon, and an amplification of, the important works, "Mikroskopische Anatomie" and "Handbuch der Gewebelehre," the appearance of which in the early fifties at once placed their author upon the topmost pinnacle of histological science. In turning over the leaves of this edition we cannot fail to recognise many an old familiar

figure, schematised after the manner which was current in the old days, but not always on that account the less actually true as a representation of the parts which it was the business of the author to describe. And we need not complain of the continued presence of these well-worn delineations, for they not only have served, but still serve their purpose, nor do they any longer stand alone as in the old days, but side by side with them there now appear representations as true to nature as the skill of the artist and of the engraver can produce, and exhibiting the intricacies of structure of cells and tissues such as only the most modern microscopes and methods have been able to reveal.

The first volume of this edition of "Kölliker's Histology," which appeared as long ago as 1889, and is itself twenty-two years subsequent to the publication of the previous edition, deals with cell-structure, with the simple tissues, with the structure and formation of the bones, of muscles and of the integument. The second volume, consisting in all of 874 pages, is devoted entirely to the finer structure of the nervous system! From which statement, combined with the reputation of the author, it will be rightly inferred that the volume is indeed a compendious account of the structure of this, the most important, system in the body, such as has never previously been in the hands of the student. And what constitutes the most remarkable fact regarding this part of the work, is that it is an actual record of personal observations, not as with most works of the kind, mainly a *rechauffé* of the observations of other people. Needless also to add, that the methods used are of the most modern description, and that the illustrations are both clear and abundant. If Kölliker had never written anything besides this monograph of the structure of the nervous system, his reputation would have been sufficiently made. What that reputation is, with the unremitting work of sixty or more years superadded to this achievement, is known to the whole world.

The second book upon our list is one of an entirely different type, and, it may be added, of a type which we are accustomed to associate with French rather than with German authors. It gives a clear and succinct account, firstly, of the chief modern histological methods, secondly, of the structure of the cells and tissues, and thirdly, of the organs of the body, the whole being illustrated by excellent drawings, which are entirely new, and which give a stamp of originality to the work. Moreover, the reproduction of the drawings leaves little or nothing to be desired, and with the exception of one or two, which only purport to be diagrams, it will at once appear that they are on the whole extremely good representations of structure. If there is any fault to be found, it is in the somewhat meagre manner in which the central nervous system is dealt with. On the other hand, it must be admitted that to deal with this at any length, would necessarily have carried the dimensions of the book beyond what may be justly regarded as the limit of an ordinary text-book for students; which is the standard aimed at in the work before us.

The third book is one of a much more ambitious character, as the title sufficiently indicates. The aim of the author is to give a comparative account of the minute structure of every organ of the body in the whole range of Vertebrata. Since the classical work of Leydig appeared forty years ago—a work which may still be referred to by the student with manifest advantage—no adequate attempt has been made to provide a comparative account of the structure of the body, and the literature of the subject is so enormous, and the amount of material that would be required to be studied so prodigious, that no one person could by any means adequately expect to cope with it. It is but fair to say that this is recognised by the author, who, in his preface, refers to the probable necessity of the work being taken up and continued by others. The present instalment deals with the comparative anatomy of the stomach alone, in a volume of 543 royal octavo pages. Beginning with the structure of this organ in fishes, it continues with it through various amphibia, reptiles, birds and mammals, concluding with man! The book is mainly a compilation, but the fullest references are everywhere given; and therefore, although it lacks the interest which more originality would have conferred upon it (in which respect it differs conspicuously from Leydig), there can be no doubt of its value as a book of reference for all who are working either at the histology or physiology of the organ dealt with. About thirty pages are occupied alone by the titles of works referred to, and this will give some idea of the extensive literary researches which the author must have made in order to render the work as complete as it is. The illustrations are of two kinds, viz. figures on wood or zinc throughout the text, with a certain number of lithographed plates at the end of the book. Neither the author nor the publisher has spared pains to render the work excellent of its kind, and it is to be hoped that future instalments may each require far less time to produce than the seven years which the author admits that he has devoted to this present part.

It is certainly not a little remarkable that after the lapse of many years without the appearance of an important work on histology in the German language, three books, such as these, so different from one another, but all in their way important, should have appeared almost simultaneously. The fact may probably be taken as a sign of the revival of active interest in general histology, most of the interest of histologists having of late been centred upon the structure of the cell and the relations of the cells of the nervous system to one another.

E. A. SCHÄFER.

ASPECTS OF GARDENING.

A History of Gardening in England. By the Hon. Alicia Amherst. Second edition. Pp. xiv + 405. (London: Bernard Quaritch, 1896.)

UNTIL attention is specially drawn to the subject, the variety of the interest attaching to gardens and to gardening is not realised. One man estimates his garden by the amount and quality of the produce it yields for his table. Another finds his æsthetic sense satisfied by the flowers it contains. The exercise and recreation afforded by garden pursuits are keenly appreciated by yet another class; whilst to the naturalist cultivated plants are living beings, replete with all the interest begot of the study of the phenomena and functions of life.

In the garden the student may obtain a knowledge of form, structure, and affinity with greater facility than in the field or in the museum. In the garden, too, he can prosecute his experiments, even upon living things, without the chance of his objects being misinterpreted, with no fear of exciting the ire of well-intentioned sentimentalists, and no risk of being harassed by restrictive legislation.

On another side the artist has in the garden scope for the realisation of his ideas, be they in an artificial or formal direction, or in one that is, or is supposed to be, natural.

As the surroundings and conditions are so extremely varied, so there is corresponding diversity in practice. There is, in fact, ample room for differences of opinion and for diversities of taste; unfortunately, we must add for controversy, not always so amiably conducted as the nature of the subject would seem to necessitate.

Miss Amherst, in presenting to the public a history of gardening in England from the earliest times to the middle of the nineteenth century, has, with few exceptions, to which we shall hereafter refer, neglected none of these different aspects of gardening.

It does not appear from her book that she is herself a specialist in horticulture, in botany, or in landscape gardening. But that she is endowed with sympathetic intelligence, aptitude for research, and love of her subject, is evidenced throughout. Her book is well planned, well put together, and accurately, yet withal pleasantly, written. It must form for a long time the standard work on the subject.

Of course the history of gardening is in its degree the reflex of that of the period. At one time gardens were enclosed within monastery walls or castle garths. They were small in extent, and utilitarian in object. As more peaceful times came, the gardens became less restricted, both in space and in object. The utilitarian side was not neglected, but an increasing sense of security led to greater refinement and to a greater appreciation of the elegancies of life. At the same time travel became easier, and travellers more numerous. The consequence of this was that "outlandish plants" were freely introduced. Art also made its way into the garden as into other departments, and, as we have seen, it manifested itself in two opposite directions. Science found her place in the botanic gardens and in the various experiments made by the curious, experiments to which, in very large measure, we owe the profusion and excellence of the flowers and fruits of the present day. Nowadays, unless we except Orchids and some few other plants, more is done by hybridisation and cross-breeding of already introduced plants than by the importation of new and hitherto untried subjects.

The plants of to-day are largely products of the gardener's skill. There is nothing in nature precisely corresponding with the tuberous Begonias. They have originated from repeated processes of hybridisation and cross-fertilisation, and to some extent they reproduce their kind as ordinary species do. Neither Japan nor China can show in a wild state such Chrysanthemums as now excite the wonder of the spectator. They are the issue of cross-fertilisation, rigid selection, and of the suppression of some buds to the advantage of one only.

The enormous advance in commercial horticulture—in what is called market-gardening, more particularly—is hardly touched on by Miss Amherst, perhaps because she did not consider that it came within the scope she allotted to herself. It is nevertheless, so far as gardening goes, the great feature of the day, and when confronted with the depressed state of agriculture, it affords a marvellous contrast for the consideration of the economist and statesman, as well as for the historian of gardening.

GEOMORPHOLOGICAL SPECULATION.

Grundriss einer exacten Schöpfungs-Geschichte. Von Hermann Habenicht. Mit 7 Karten-Beilagen und 2 Text-Illustrationen. Pp. viii + 136. (Wien, Pest, Leipzig: A. Hartleben's Verlag.) [Preface dated 1896.]

THIS "exact history of creation" is neither so clear nor so credible as the first chapter of Genesis, with which the author tries to harmonise it, nor does it appear to come any nearer to agreement with the views of modern geologists; yet the aim of the work is distinct and noble. The preface begins:—

"This book is the fruit of nearly forty years' professional study of the known surface of the Earth and of Geophysics, chiefly from the morphological point of view, according to the best existing original works which, for the most part, were official. It is the first attempt *to refer to one single fundamental natural law*, not only the position and structure of our planet, its continents, ocean-basins, and great mountain chains, but also the conditions of the stratification of rocks, fossilisation, earthquakes and volcanoes, ice-ages, &c., even the endless profusion of the organic world and the origin of species itself. It is the first attempt to coordinate the definitely ascertained facts of Astro-, Geo-, and Experimental-Physics."

It is strange that forty years of that laborious and conscientious study, which have made the name of Habenicht illustrious in his own department of cartography, did not reveal to him even one prior attempt to simplify the bewildering history of the formation of the earth. Mankind is surely not so backward in cosmical speculation as that seems to imply. But of course these speculations do not appear in official reports; they see the light in imaginative pamphlets and books published usually at the author's risk, we fear, in more senses than the financial.

This new attempt is a republication of papers which have appeared at various dates during the last twenty years, and are now grouped to form three parts. Part i.—"Scientifically Observed Facts"—deals with the sudden appearance of new stars, the cooling of the earth experimentally considered, and the seismic problem, the last-named illustrated by a map showing the active volcanoes and axes of greatest seismic activity of the world constructed in 1889. Part ii.—"Traces of Facts from the Geological Past"—cites, amongst others, the works on the flood of Sir Henry Howorth and the late Sir Joseph Prestwich, which appear to have greatly influenced the author. Part iii.—"The Theory of the Spherical Crater-basin"—reveals the unifying law which simplifies the history of creation. It is the law of world-blisters. As the earth cooled originally, various gases extricated themselves from the fluid magma, and collected under

the crust, gradually heaving it up into a dome which burst, allowed the gases to escape, and its fragments fell back, leaving a crater-basin like those on the moon. As the crust strengthened the blisters grew larger (all Asia was required for one), and their edges were higher after the collapse. The hollows gradually filled with rain, and sediment being washed into them, gave rise to such geological forms as the Paris or the London basin. Herr Habenicht shows immense ingenuity in fitting his hypothetical blisters to the morphological lines of the earth, and the maps in the book are most interesting. If the theory were put forward as an exercise in scientific imagination, it would be clever and admirable; if it be, as we fear, a serious attempt to interpret existing geographical forms, it is valueless now De Morgan is dead, and might be mischievous. The theory is not tested; it is built to fit a certain interpretation of facts, and the demonstration that it fits that interpretation is put forward as evidence of its truth. Some concluding remarks on Darwinism and evolution are of a type once common in this country, but now becoming rare enough to make it worth while to signalise the discovery of a belated specimen. H. R. M.

OUR BOOK SHELF.

A New Speculation on the Past and Future Temperature of the Sun and Earth. By W. H. Pp. 198. (London and Manchester: John Heywood.)

YET another book designed to show men of science the imperfections in their theories, and to enlighten them as to the constitution of the universe. The main contention of the author is that the sun and earth are not cooling bodies, and that they have never formed part of the same nebulous mass. He considers that the sun is not really hot, but merely the cause of heat in sentient beings; which seems to be a distinction without a real difference. The poorness of the argument becomes even more obvious by the comparison of the molecules of the sun with the molecules of a piece of iron beaten upon an anvil. Of course we know that the molecules of the iron only have their energy increased by the blows of the hammer, and of course we know that heat *quâ* heat does not exist until it affects sentient organisms. But to argue from this that the sun is a cool body, and to say "that which we call heat in the sun is but molecular motion," is as inconclusive as would be a statement that the sun is a dark body, and that which is called sunlight is but a motion of the ether.

The author does not stop at this: he essays to prove that the sun is a hollow sphere or a system of spheres, and regards the proportions of oxygen and nitrogen in the earth's atmosphere as nicely adjusted for the comfortable existence of man; in which *post hoc ergo propter hoc* reasoning he follows the young curate who animadverted upon the beneficence of Providence in making rivers run near the towns. But enough has, perhaps, been said to reveal the character of the book. There is, however, one other little point to be mentioned. The author's chief objection is to the nebular hypothesis, but he does not appear to have got beyond that stage of astronomical knowledge when every nebula was regarded as a star cluster not yet resolved into its components. He does not think there are nebulæ anywhere in the universe, and he completely ignores spectroscopic evidence as to their existence. "Can the astronomer ever say," he remarks, "he has discovered a nebula that no power of the telescope can resolve? But suppose there was a nebula indeed, one undisputed and undisputable, what is that to me?" What indeed? all the known nebulæ and all the astronomers, will not induce "W. H." to refrain from demolishing what he regards as scientific heresies. The occupation pleases him, and it does not hurt either fact or theory. R. A.

Light. By W. T. A. Emtage, M.A. Pp. 352. With 231 illustrations. (London: Longmans, Green, and Co., 1896.)

THIS book is a new volume in the series of science manuals published by Messrs. Longmans to meet the requirements of the advanced stage of the science subjects of the Science and Art Department. It is one that should find favour with students in general, as the various parts of the subject dealt with are for the most part clearly and concisely explained. There is also no lack of illustrations, which is always a very important point in a book treating on optics, especially in the case where it may be read by students who are not all too familiar with the subject. The scope of the book will have already been gathered from the fact that it follows the Government Syllabus. We may mention, however, that the author has employed elementary mathematical treatment, having limited himself to little more than an advanced knowledge of trigonometry. Attention has been paid also to the experimental side of the subject, methods of making experiments and optical measurements being given.

To those wishing to obtain a good general insight into the principles of optics and optical instruments, the book can be recommended.

Tables for Iron Analysis. By John A. Allen. Pp. vii + 85. (New York: John Wiley and Sons. London: Chapman and Hall, Ltd., 1896.)

CHEMISTS engaged in making analyses in connection with the manufacture of iron and steel, will find these tables very serviceable. The tables are of ten classes: one set "converts a weight of a definite chemical compound obtained when a certain quantity of substance is analysed into the percentage of an element or oxide contained in the substance," and the other set "converts into one another, equivalent percentages of an element or oxide, and of a compound of which the element or oxide is a constituent." The work of technical chemists will be greatly assisted by this practical collection of conversion numbers.

Notes for Chemical Students. By Prof. Peter T. Austen, Ph.D., F.C.S. Pp. 111. (New York: John Wiley and Sons. London: Chapman and Hall, 1896.)

THERE are certain knotty points which teachers of elementary chemistry know to be difficult for students to understand, and which are not sufficiently considered in small text-books. Such are the nascent state, absolute existence of masses and molecules, smoke rings and vortex atoms, modes of chemical action, affinity, substitution, &c. This book aims at filling the gap in the literature of chemical teaching, and though on some points it is not any fuller than several elementary text-books we could name, it contains a number of clear and concise descriptions of topics which present difficulties to the student.

Notes of the Night, and other Outdoor Sketches. By Charles C. Abbott, M.D. Pp. 231. (London: Frederick Warne and Co., 1896.)

THIS series of nine essays contain the author's reflections on outdoor life and scenes in New Jersey. There are thoughts on gurgling brooks, on "swelling buds, and frogs astir in the warm waters of the throbbing springs," and similar subjects which move the spirit of poesy, and induce the mind to wander. Such lucubrations will not please the palate of students of science; for they are, as a rule, too nebulous and unsubstantial, but dreamy naturalists will be interested in them.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Osmotic Pressure and Ionic Dissociation.

No doubt there will be great joy in the camp of the ionists over the sinner that repenteth on seeing the letter of my friend Prof. Poynting, but I imagine that those who thought that he was about to break a lance on behalf of the opponent party will agree that he is but a fickle ally, if they do not go further and conclude that he has perhaps failed to understand the real question at issue.

All are agreed that Arrhenius and van 't Hoff and their satellites have rendered inestimable service by their generalisations, and the consequent application they have made of them; certainly the world has shown its esteem of their work. Moreover, there can be no doubt, as I stated not long ago in my presidential address to the Chemical Society, that in so far as *weak solutions* are concerned a law has been discovered which is broadly true *in mathematical form*: yet I have no hesitation in asserting that the fundamental premises on which it is based are destitute of common sense in the opinion of those who look at these matters without leaving chemical experience out of account; and I venture to think that this is not only their position, but also that of many physicists. Lord Rayleigh, in fact, in the course of his remarks on Prof. Fitzgerald's Helmholtz lecture at the Chemical Society in January last, actually said:—"It is to be hoped that chemists will take into grave consideration the emphatic warning that Prof. Fitzgerald has given, particularly as to the danger of supposing that there is any dynamical similarity between the condition of a gas and that of a dissolved substance in a liquid. . . . there is possibly a risk of pushing formal analogies too far, and of supposing that there is a real dynamical similarity, whereas perhaps there is only a similarity in mathematical law."

I for one require no better support than this, and shall continue to be, as I have been from the outset, a determined opponent of what, I think, may fairly be termed the nonsensical hypothesis of ionic dissociation, for there is no other appropriate term for a view which asserts that hydrogen chloride and a few other compounds are so loosely strung together that they fall to pieces when dissolved in water: out of sheer fright, it would seem, as no valid motive is suggested for such self-sacrifice; and no such charge of unprincipled levity of conduct is brought against the vast majority of compounds other than a few acids and akalies! I believe the view in question to be in entire opposition to the teachings of chemical experience; inapplicable to the explanation of the greater number of facts. It is a sign of the times that such views can obtain the credence that has been accorded to them; proof how little we care to criticise in these days when authority counts for so much—especially in Germany. On the other hand, the facts generally seem to be in entire accordance with an association hypothesis: and if Prof. Poynting would seriously devote himself to putting such an hypothesis into mathematical form, he would be rendering the one great service that is required of physicists in this connection. All that is needed, I imagine, is to show that the equations deduced from the one hypothesis are equally compatible with another diametrically opposed to it—surely a small thing to ask of mathematicians.

The dialectical skill of those who are seeking to impose on the scientific world the ionic dissociation hypothesis as the only true faith is very remarkable. They *must* be near relatives of Maxwell's demons, judging from the adroitness with which they extricate themselves from seemingly hopeless positions—no matter at what sacrifice, and the infinite elasticity of their views—which, indeed, are often so elastic that it matters little which way the argument turns. For example, in a recent discussion on accumulators at a meeting of the German Electro-chemical Society, the possibility of lead peroxide ions existing in solution having been suggested, it was urged that the presence of a few such would not suffice: whereupon Prof. Nernst said that this was no difficulty—it was only necessary to bear in mind the readiness with which silver was separated from cyanide solutions, in which the number of silver ions was inconceivably small. If so few will suffice, why not try to do without them altogether, one is tempted to say. As another instance, I may refer to Mr. Whetham's diplomatic action in at once offering to conclude a treaty of peace with Prof. Poynting by conceding the willingness of the ions, if necessary, to bear the water molecules on their backs or be chained to them as galley-slaves: formerly we were assured that ionic dissociation was purely platonic suicide, and that there were no Rhine maidens in the stream to attract the ions apart and bear them away. Of course, in preferring these terms, the effect is carefully left out of account which such copulation would have on the mystic charges carried by the ions; hypothetical burdens which place them on a level far superior to that of any commonplace independent molecule, serving to keep them in bounds, and which permit of subtle distinctions being made between ordinary and ionic dissociation—making the latter not dissociation at all, in fact, for ionists certainly ask both to keep their cake and eat it. Again, Mr. Whetham, I note, refers to ionic velocities. To me it seems impossible to believe that the ions are the infinite sluggards indicated in conventional time-tables such as those issued under Lodgian editorship—apparently with his approval; with all due deference to such authority, we must decline to accept so slow a service, the more if we are to believe that the gaseous and liquid states are in any way dynamically comparable. It may perhaps be argued that the charges act as brakes—but surely such an argument is double-edged, for if we are to suppose that the freedom of the ions be thus clogged, liberty can scarcely be theirs to act as ordinary gaseous molecules in effecting pressure.

I am free to confess that my condition of belief as to the existence of "atomic charges" and any form of ionic *dissociation* is purely agnostic—but this is clearly an attitude which is abhorrent to those who are now arrogating to themselves the position of superior persons to whom has been granted the mission and plenary powers to reform an ancient society long steeped in superstition: to wit, the chemists. But the chemists' chief concern has been, and still is, to establish facts, and by so doing, they have probably got nearer to the inner workings of nature than any other class of investigators: for such, the new inquisition has no terrors.

In a paper, of which the Physical Society—in a most aggravating and reprehensible manner—publish but the first two pages in the current number of their journal, Prof. Larmor tells us "that the facts of chemical physics point to electrification being distributed in an atomic manner, so that an atom of electricity, say an electron, has the same claims to separate and permanent existence as an atom of matter." But is not this view based on a particular—I venture to say, a narrow—interpretation of the facts of electrolysis? Do the facts of chemistry point to such a view? Those who cultivate chemical physics have a way of putting chemistry altogether aside, as a mere unimportant detail. Does it not entirely leave out of account the difficulties which the existence of so-called molecular compounds introduces? Do physicists—do chemists even—in any way appreciate these? I have already elsewhere contended that if there be an electron, it must be capable of acting piecemeal—no discussion of the question from this point of view has yet been attempted.

The facts must not be left out of account! There are many gifted mathematicians and physicists at the present day who are showing willingness to take such matters into consideration, but they are too prone to accept their facts at second-hand—often from those who, although nominally chemists, are destitute of *chemical feeling*—an indefinable instinct which, however, has a very real existence: consequently two parties are arising with no common ground between them.

Surely there is no need to be in so great a hurry—it is no disgrace to admit that we cannot yet explain all the mysteries of the universe. Lord Kelvin told us recently that he knew no more of electric and magnetic force, or of the relation between ether, electricity and ponderable matter, or of chemical affinity, than he knew and tried to teach his students of natural philosophy fifty years ago in his first session as professor. And it should also not be forgotten that one to whom all yield respect has written: "It is extremely improbable that when we come to understand the true nature of electrolysis we shall retain in any form the theory of molecular charges, for then we shall have obtained a secure basis on which to form a true theory of electric currents, and so become independent of these provisional theories." (Clerk Maxwell, "Electricity and Magnetism.")

Meanwhile, do not let us pervert the morals of our student youth by talking glibly of atomic dissociation, and using a dogmatic phraseology which leads them to believe that we have

reached finality and gives them totally false ideas as to what *we know*. It is so easy to make use of all that is good in the new work by substituting a neutral phrase, such as coefficient of activity, for coefficient of dissociation—for all that we have really done is to recognise that certain compounds exercise a superior degree of activity, and to measure the relative degree of activity of these. To substitute for common-sense expressions which all understand—and even to promulgate at County Council expense—a set of shibboleths which commit us to a definite hypothetical interpretation of the facts is unnecessary, undesirable, and unscientific. Such metaphysical speculation is obviously doing the deepest injury to the cause of exact science.

HENRY E. ARMSTRONG.

On the Publication of Original Work.

MUCH has been written and said as to the facilities for the publication of original researches in this country. It is now becoming quite a regular custom for English comparative anatomists to publish their work in a foreign journal. Not only the morphologist, but also the systematist has found this necessary. One is naturally led to inquire why—with so many learned and wealthy societies in our midst—publication cannot be effected so as to give the author the necessary printing and illustration in a style comparable with that of continental journals, and with a minimum amount of delay?

In this country the only sources of publication for monographs on zoological subjects are the *Phil. Trans.* of the Royal Society, the *Trans. Zool.*, and the *Trans. Linn.*, and of these it would naturally be supposed that the *Trans. Zool.* is pre-eminently the place for such publications. But it will scarcely be credited that a wealthy Society like this, for some unknown reason, should allow in some cases as long as two-and-a-half years to elapse before publication of material received. Thus I find, on referring to volumes of the *Trans.*, a paper received November 1, 1892, read December 20, 1892, was published in February 1895. Another, received December 5, 1892, read February 14, 1893, was published October 1895. Still another, received October 14, 1893, read November 7, 1893, was not printed till April 1896! These are examples chosen at random.

There seems no obvious reason why any or all of these should not have been published within six months from the date of reception. A fourth instance, which I here wish to narrate, will, I trust, serve the purpose of showing zoologists the need of some more speedy means of publication.

In the winter of 1894–95, I completed a piece of work on the suprarenal capsules in fishes, and was advised to offer it to the Zoological Society for publication. The paper was received, in the first instance, on June 6, and I hoped it would have been taken as read at a meeting of the Society held in that month. It was, however, not read till November 19, when Prof. Howes was good enough to undertake it for me. It was ordered for publication in the *Trans.*, and now (November 14, 1896), nearly twelve months from the date of reading, I have not yet received my proofs. Surely such extraordinary delay as this ought not to be necessary.

During such a long period I have found it necessary to keep pace with much literature bearing upon the subject; but more than this, I have just suffered the chagrin of seeing a paper embodying a large slice of my results published by an Italian journal.

Perhaps some others will be found to agree with me that some means ought to be found of getting earlier publication in comparative anatomy and allied subjects. In the minds of many, I feel sure, there can be little doubt that the Zoological Society should undertake such work.

I do not wish to make out that I have been treated exceptionally, or in any way unjustly. My experience has been no worse than that of many others. The officers of the Zoological Society have treated me with every courtesy, and have even allowed me to publish an abstract of my paper elsewhere. But, nevertheless, I fail to see why the work could not have been published within six months from the time of reception.

SWALE VINCENT.

Mason College, Birmingham, November 14.

Cultivation of Woad.

As supplementary to the article on the cultivation of woad, by Messrs. Darwin and Meldola, in NATURE for November 12, it may further be stated that this plant has been grown besides at Parson Drove, at Boston, Wyberton, and Algarkirk, in the Lincolnshire Fenland, for a very long period. An account of its cultivation, with details of the process and preparing it for use, will be found in Arthur Young's "Agricultural Survey of Lincolnshire," published at the end of the last century. A more modern account will be found in "The History of the Fens of South Lincolnshire," recently published. This plant is not cultivated in any other part of England than the Fenland, and the total area grown altogether yearly does not, as a rule, exceed fifty acres. It requires very good land for its cultivation, and much rich old pasture land has been broken up for the purpose, for which as much as 10*l.* an acre has been paid for rent, and 150*l.* to 200*l.* for purchase of the freehold. The price obtained for woad was formerly about 25*l.* a ton, but it has declined in recent times to 9*l.* or 10*l.* The woad, when prepared for market, is not used for dyeing, but is mixed by woollen dyers with indigo to excite fermentation and fix the colour.

Boston. W. H. WHEELER.

WITH reference to your article on "An English Woad Mill," may I mention that Billingsley, in his book, published in 1798, on "Agriculture in the County of Somerset," mentions woad as an important article of cultivation, raised principally in the neighbourhood of Keynsham, near Bath. The mode of preparation, described by Billingsley as in use one hundred years ago, closely resembles the description given in NATURE as in use at the present day. He adds that the crop is a profitable one; so lucrative, indeed, that few farmers who can raise it, ever discontinue the practice. He also mentions that it was cultivated by one Harvey, more generally known as the "Woad-man," at a farm near Mells. The cultivation of woad does not appear, therefore, to have been so very rare in the last century; but whether it is still cultivated in Somersetshire, I am unable to say. ROSA M. BARRETT.

Kingstown, Dublin, November 14.

"X-rays with a Wimshurst Machine."

THERE is an error, for which I am responsible, in my letter of July 24 (p. 31). The words kathode and anode should be interchanged in one sentence, which should then read thus:—"The same reasoning would indicate that it would be well to make the *anode* convex towards the *kathode*, and fairly small. . . ."

Eton, November 13. T. C. PORTER.

FLYING BULLETS.

QUITE recently M. Tissandier, editor of *La Nature*, received from Prof. Mach, formerly Professor of Physics at Prague, now Professor of the history and theory of inductive science at Vienna, a letter containing a photograph of a bullet in motion (Fig. 1). The photograph was taken by Prof. Mach's son, and shows most clearly the waves of air caused by the bullet's passage through the atmosphere.

M. Tissandier, wishing for an explanation of the experiment and description of the apparatus, wrote to Prof. Mach, and received the accompanying diagram (Fig. 2), with the following short account. "My son took the photographs of the bullet by using a spherical silvered-glass mirror. MM is the mirror, P the bullet, E the screen, B the photographic apparatus, S the spark. The bullet causes a sonorous wave, by which the Leyden jar is *mechanically* discharged, and produces the spark S."

It may be added that the description of his first apparatus appeared in *La Nature* of 1888.

Our readers are also familiar with the photographs of flying bullets which were exhibited at the soirée of the Royal Society in May 1892. These were results of experiments made by Mr. Vernon Boys, obtained by a modification of an old method. One slide showed the small pieces of paper scattered by the bullet passing through a sheet, and these were carried on in the same direction as the bullet itself; whereas in the case of a magazine rifle bullet going through a sheet of glass, the shattered pieces of glass appeared to travel in an opposite

direction to the bullet. Various kinds of bullets were used for these photographs, some of aluminium, in

FIG. 1.—Photograph of a bullet in motion.

order to obtain a greater velocity, which varied from 750 to 3000 feet per second; the former being the

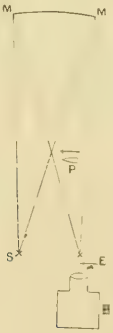

FIG. 2.—Arrangement for the photography of a bullet in motion.

average velocity of a pistol shot, the latter of a magazine rifle.

SIR B. W. RICHARDSON, F.R.S.

SIR BENJAMIN WARD RICHARDSON, whose death we regretfully announce, will be remembered more widely on account of his many lucid contributions to popular medical literature, and as an attractive lecturer on scientific subjects, than for his additions to medical knowledge. His great and versatile talents do not, however, diminish his claims to distinction as a physician of much originality of mind and a careful investigator; and these are the qualities which has earned for him the high esteem of men of science.

Sir Benjamin Richardson was born at Somerby, in the county of Leicester, in 1828, and graduated in medicine at the University of St. Andrews in 1854. After a short experience as general practitioner, he removed to London in order to devote himself to medical and physiological research. In 1856 he obtained the Astley Cooper Triennial prize of £300 for the best essay on the coagulation of the blood, and from that time forward his life was one of incessant professional and literary activity. He devoted much time to the investigation of the action of anæsthetics, and to an endeavour to discover some agent which should be superior to chloroform: but, of the many compounds with which he experimented, only one, the bichloride of methylene, has in any way held its ground, and that only in the hands of a few administrators. This inquiry led him to the discovery in connection with which his name is best known, viz. the application of ether spray for the local abolition of pain in surgical operations. Among the many other subjects which he advanced by experimental study are: the restoration of life after various forms of apparent death; methods of killing animals without the infliction of pain; effects of electricity upon animal life; and alcohol in relation to its action on man. He also introduced into medical and surgical practice many valuable preparations, among others the ethylate of sodium; and his investigations largely contributed to the attainment of a working knowledge of the properties and uses of nitrate of amyl. In 1864, "in recognition of his various contributions to science and medicine," he was presented, by six hundred members of his profession, with a testimonial consisting of a microscope by Ross and one thousand guineas.

Sir Benjamin Richardson's contributions to magazines, journals and transactions are innumerable. He originated and for a time edited the *Journal of Public Health*, afterwards called the *Social Science Review*, and for the last twelve years he has maintained a quarterly medical journal, the *Asclepiad*, of about 150 pages, every line of which has been of his own composition. On the very day of his fatal seizure he had completed the revision of the proofs of a new book entitled "Memories and Ideals." He was elected a Fellow of the Royal Society in 1867, and was the Croonian lecturer in 1873. He received the honour of knighthood in 1893, and, among other distinctions, was a Fellow of the Society of Antiquaries, of the Royal College of Physicians of London, and of the Faculty of Physicians and Surgeons of Glasgow. He was M.A., M.D., and LL.D. of St. Andrews; Fothergillian gold medallist; and past President of the Medical Society of London.

Thus for more than forty years Sir Benjamin Richardson devoted his energies to the solution of the question, "How shall pain, disease—nay, death itself as an enemy—be swept from the earth, as vanquished enemies of every race?" By his efforts to relieve pain and remove the pangs of death, and for the attention which he gave to other questions connected with his noble profession, he claims the gratitude of humanity.

Sir Benjamin Richardson leaves a widow and two sons and a daughter.

NOTES.

A MONUMENT in memory of Father Secchi, the former Director of the Collegio Romano Observatory, has been erected at Reggio (Emilia), where he was born. The sum of 78,000 francs was publicly subscribed for this purpose.

THE *British Medical Journal* states that the long-standing question of providing a statue to Darwin in his native town (Shrewsbury) has been settled by the Shropshire Horticultural Society undertaking to defray the entire cost, estimated at from £1000 to £1200.

THE death is announced of Dr. F. Saccardo, professor of natural sciences at the school of viticulture at Avellino, a recognised authority on the diseases of the vine, and a writer on lichenology.

THE competition of horseless carriages for the prizes, amounting to 1100 guineas, offered by the *Engineer*, will take place at the Crystal Palace next May. The trials were to have taken place during the past summer, but in deference to the wishes of intending competitors it was postponed until next year.

AN application of Röntgen rays to palæontology is recorded in the *British Medical Journal*. M. Lemoine, of Rheims, recently showed to the Paris Biological Society the *clichés* of Röntgen photographs of fossils embedded in the chalk strata of Rheims. M. Lemoine is reported to have thus photographed a series of fossil birds, reptiles, and mammals.

WE regret to announce the deaths of the following men of science abroad:—Dr. E. A. G. Baumann, Professor of Physiological Chemistry in the University of Freiburg; Dr. R. Kerry, Director of the Bacteriological Institute of the Agricultural Ministry at Vienna; Dr. Eugen Sell, Extraordinary Professor of Chemistry in the University of Berlin; and Dr. S. Cornelius, Titular Professor of Physics in the University of Halle.

THE sixtieth anniversary of Prof. James Hall's public services to science, as State Geologist of New York, was celebrated by a special meeting at Buffalo, during the recent assembly of the American Association for the Advancement of Science. A full report of the appreciative remarks made on that occasion by Prof. Joseph Le Conte, on behalf of the Geological Society of America, with the addresses and papers presented as tribute to the Nestor of palæontology and the founder of American Stratigraphy, appears in the issue of *Science* for November 13.

WE learn from the *Times* that Mr. David Robertson, a well-known Cumbrae naturalist, died at Millport on the 20th inst., at the age of ninety. He was a native of Glasgow, but for the last forty years he lived at Millport, and devoted much attention to the study of the natural history of the west of Scotland. In company with Dr. John Murray, of the *Challenger* expedition, he dredged the greater part of the Firth of Clyde; and largely through Dr. Robertson's efforts the foundation-stone of a permanent marine station was lately laid. Two years ago the University of Glasgow conferred on him the degree of LL.D.

WE regret to announce the sudden death of Mr. Arthur Dowsett at his residence, Castle Hill House, Reading, on Friday morning, the 6th inst. Mr. Dowsett was well known to a large circle of friends as an enthusiastic lover of natural history, and he had made large and valuable collections of ornithological and entomological specimens. He was one of the founders of the Reading Natural History Society, of which he acted as president from 1882 until the time of his death. He was scarcely ever absent from one of the Society's indoor meetings, and had greatly endeared himself to all the members by his kindly genial disposition and unfailing readiness to do anything to further their aims and objects. He was a Fellow of the Zoological and Entomological Societies.

IN his presidential address to the Royal Statistical Society, last week, Mr. John Biddulph Martin counted as enemies to statistical science the laborious compilers of figures which were of no value when obtained, and those who aimed at minute accuracy in figures when it was impossible to estimate, save approximately. The physical investigator who expresses his results to four or five places of decimals when he cannot determine one of the factors within a probable error of one per cent., comes in this category. It was through extravagances of this kind that M. Thiers defined statistics as the art of stating in precise terms things which one does not know. Dealing with the graphic method of expressing statistical totals by geometrical figures, accompanied in some cases by the employment of colours, Mr. Martin regretted that the use of the method, which had sprung up automatically, had not been developed on any conventional lines. Were the employment of particular graphic forms invariably applied to the exposition of the same phenomena, and if this conventional agreement could be made international, the interpretation of statistics graphically presented would be vastly facilitated.

IN the *Mathematical Gazette* for October, Mr. R. F. Muirhead points out that Newton's law of impact as stated in text-books does not apply to cases when three or more bodies are in simultaneous collision, and, moreover, it appears that the problem is not a determinate one unless some further assumption is made. Thus in the case of three spheres colliding together, if the collisions are not perfectly simultaneous, the final velocities of separation depend on the order in which the two first collisions take place. It would be interesting to test this last result experimentally.

SEPARATE records of the rainfall in the day and night are of much greater value to medical men than a knowledge of the mean rainfall of each month. Mr. W. W. Wagstaffe points out the advisability of keeping such records separately; and he gives, in the *Lancet*, the results of ten years' observations of the relative fall of rain in the day and night at Sevenoaks, taking the day to be from 10 a.m. to sunset. The mean annual rainfall for the day was 40 inches, and for the night 60 inches. An examination of his records shows that in winter the nights are much wetter than the days, and in spring and autumn they are also wetter, but the difference is less marked. In summer the excess of rain at night is found to be much less marked than in the other seasons.

A SHORT time ago Mr. J. H. Hart mentioned, in the *Bulletin* of miscellaneous information published at the Royal Botanic Gardens, Trinidad, that there was evidence of the attack of fungi on timber or trees previous to the destruction of the wood by Termitidæ. He returns to the subject in the October *Bulletin*, wherein he states that the mycelium of a fungus could be readily traced in all parts of the tissue of a number of specimens attacked by Termites. That it is really a fungus which attacks the wood, the experiments at Trinidad prove conclusively, and that Termites follow the attack is also clearly shown. The only doubtful point is whether the wood ants do at any time or in any case attack sound timber. So far as observations at present go, it seems that the primary cause of the destruction of wood by Termites is the mycelium of some fungus.

TO the University of Illinois belongs the honour of having established, under the direction of Prof. S. A. Forbes, the first fresh-water University Biological Station in America with an adequate equipment. The centre of operations is a commodious boat, having a laboratory in which fifteen workers can be accommodated. This floating laboratory was moored at Quiver Lake, two miles north of Havana, during the past summer. How very attractive this district is, both from a scenic point of view, and from the standpoint of the naturalist engaged in investigation, may be gathered from an illustrated article in *The Illini* of November 6. Quiver Lake is the home of myriads of water-fowl; it abounds in vegetation, and the microscopical life of the water is equally abundant and varied. It seems to be a paradise for students of natural history; so we are not surprised that the full complement of investigators occupied the boat during the months of June, July, and August, and made observations of value to biological science.

THE technical papers are almost unanimous in their adverse criticisms of the recent motor car show. *Engineering* says: "To the thoughtful engineer, last week's saturnalia could not have

seen otherwise than a melancholy spectacle. . . . The proceedings only further illustrated what was pretty well known before—that at present the science of designing mechanical road carriages is in a very elementary stage, and much remains to be done before it can be claimed that a motor car has been produced fit to take its place on the highway as a commercially successful carriage, and one which can be relied upon to do general work in competition with horse-drawn vehicles." The *Electrician* remarks: "The adaption of electricity to the requirements of vehicular traffic is, in our opinion, still in the embryonic stage: and that being so, it is decidedly premature to float public companies on the basis of mere estimated profits. There is so very little to go upon, electrically speaking, and that little is so very discouraging, that no sober-minded engineer would care to countenance an appeal for funds at the present juncture, and pledge his reputation that with ordinary care the investment would, within a reasonable period, prove sufficiently remunerative to compensate for the risk run." The *Electrical Review* holds the same opinion, and shows that the scheme for using accumulator-driven cabs in London cannot be a success even with the accumulators of "special patented design" referred to by company promoters. "It behoves electrical engineers to seriously and conscientiously study the question," says our contemporary, "in hopes of some day finding the requisite and proper electric vehicle, as distinguished from the mere car of the promoting 'Juggernaut' whose pathway is strewed with the wasted gold of a confiding and credulous public."

TAILED men have again turned up. Six years ago, in the course of a visit to the Indo-Chinese region, between 11° and 12° lat. and 104° and 106° long., M. Paul d'Enjoy captured an individual of the Moï race, who had climbed a large tree to gather honey. In descending, he applied the sole of his feet to the bark; in fact, he climbed like a monkey. To the surprise of the author and his Annamite companions, their prisoner had a caudal appendage. He conversed with them, swaggered in his savage pride, and showed that he was more wily than a Mongolian, which, as the author adds, is, however, a very difficult matter. M. d'Enjoy saw the common dwelling of the tribe to which this man belonged, but the other people had fled; it consisted of a long, narrow, tunnel-like hut made of dry leaves. Several polished stones, bamboo pipes, copper bracelets and bead necklaces were found inside; these had doubtless been obtained from the Annamites of the frontier. The Moï used barbed arrows which are anointed with a black sirupy violent poison. The tail is not their only peculiarity. All the Moïs whom M. d'Enjoy has seen in the settlements have very accentuated ankle-bones, looking like the spurs of a cock. All the neighbouring nations treat them as brutes, and destroy these remarkable people, who, the author believes, to have occupied primitively the whole Indo-Chinese Peninsula. The Moï skulls described by MM. Verneau and Zaborowski were certainly by no means those of pure natives: they were taken from graves; but the settled Moï burn their dead, and place the ashes in bamboo pots, or in ratan baskets, considering their spirits as protective divinities. As this somewhat sensational account has been published by our esteemed contemporary *l'Anthropologie* Tome vii., No. 5), we must treat it with respect; and we hope it will not be long before these tailed men are carefully described by a trained scientific observer.

A VERY remarkable archæological find was made this summer near Perm, on the hilly left bank of the Kama, at the village Glyadenovo. In June last, M. Sergueeff, a member of the Perm Archives Committee, discovered at that spot traces of an earthen fort and of an extensive burial-place of the old, still problematic inhabitants of old Russia, the so-called Chuds. Systematic excavations having now been made in the five feet thick layer of bone-ashes of that burial-place, perhaps the richest known collection of Chud implements was unearthed. No less than 100 earthenware vessels, and cart-loads of broken pieces of earthenware were found. These broken pieces are ornamented with all sorts of figures, giving a full insight into the life of the inhabitants. Men sitting on horseback and in small boats, nine engravings of bees and flies, fifty-nine engravings of birds, 102 of different mammals, ten of snakes, were found on that earthenware, besides three masks and one head of mammals, one big silver plate representing a man who stands on some animal, and eight smaller silver plates, 141 bronze plates, several bronze statuettes, and an immense number of rings, stars, bells, small models of sledges, thimbles, arrow-heads, hatches, knives, 390 gilded bronze pearls, fishing hooks, skulls of stags, various carnivorous animals, &c., were discovered. In short, a full picture of the life of the Chud is given by this unique collection; the only difficulty being now to find where to house it, as the Perm "Museum" is nothing but a small apartment, hired for the exhibition of some antiquities of this extremely interesting region.

THE increasing part played by reading in the life of civilised man has resulted in the wide prevalence of myopia, astigmatism, and kindred disorders. Myopia would, however, be rare if the eye were never fatigued; so a paper by Harold Griffing and S. I. Franz, in the *Psychological Review*, on the physical conditions of fatigue in reading, and the best means of avoiding it, should be of service. From their experiments the authors conclude that the size of type is the all-important condition of visual fatigue. No type less than 1·5 mm. in height should be used, the fatigue increasing rapidly even before the size becomes as small as this. The intensity of illumination is apparently of little consequence within the limits of daylight in well-lighted rooms. Very low intensities, less than from 3 to 10 candle-metres, are sources of even greater fatigue than small type, and 100 c.m. may be considered a safe limit. White light rather than yellow light should be used for artificial illumination. The form of the type is of less importance than the thickness of the letters. White paper should be used, though it is possible that the greater amount of light reflected from pure white paper may cause some fatigue. Additional "leading" or spacing between the lines is also recommended. These conclusions should be especially known to publishers of school books.

FROM the Tōkyō Mathematico-Physical Society we have received a copy of their *Kiji* (Proceedings), including papers by Prof. D. Kikuchi, on Agima's method of finding the length of an arc of a circle, and by K. Tsuruta, on the magnetisation of iron wires traversed by electric currents. The latter paper is illustrated by diagrams showing the changes which take place in the curves of magnetisation, of susceptibility and of cyclic magnetisation when currents of different strength are passed through the wire. The author finds that the effects are the same in whatever direction the current is passed through the wire, in this respect differing from a result previously obtained by Prof. C. G. Knott.

THE revival of an old controversy in a new form, in connection with the application of corpuscular and undulatory theories to kathodic rays, has led to a rather interesting mathematical investigation by Dr. A. Garbasso, published in the *Atti dei Lincei*. The author's object was to determine whether the well-known effects of an electric or magnetic field in deflecting these rays could be accounted for on the undulatory theory, and he considers particularly the effect of a uniform magnetic field in imparting to these rays a helicoidal form. The equations obtained by Dr. Garbasso seem to show that the latter phenomenon cannot be accounted for on the hypothesis of trans-

verse vibrations, at any rate if the surfaces of equal refractive index are parallel planes. Dr. Garbasso does not seem, however, to introduce any considerations of the "Hall effect" into his calculations; whether the latter phenomenon has any bearing on the question or not, is quite another matter.

DR. E. ODDONE has recently examined the seismic record of Liguria during the last century (1796–1895), in order to determine whether the frequency of earthquakes in that district is subject to any periodic laws. The record is a non-instrumental one, and the results derived from it have not therefore the same value as those obtained from a seismometric catalogue. Dr. Oddone shows that the supposed nocturnal prevalence of earthquakes is here insensible, but there is a daily period with its maximum between 6 and 7 a.m. The two halves of the century do not exhibit the same distribution of earthquakes throughout the year, and in the latter half (during which the record is most complete), earthquakes are equally numerous in the summer and winter months. They are less frequent during years of maximum solar activity, and *vice versâ*, so that there appears to be a period of eleven years, and possibly also one of about twice this length.

WE have received a work on Earth Temperatures at Mustiala, by Dr. T. Homén, being part 9, vol. xxi. of the *Acta* of the Society of Sciences of Finland. The Agricultural Institute of Mustiala is situated in lat. 60° 49′ N., and long. 23° 47′ E.; the observations were taken both near the Institute and at the woody district of Heinäis, about seven miles to the north, during the years 1885-94, at various depths, and are printed *in extenso*, together with monthly means and yearly extremes. They are discussed with a view to showing the influence of rainfall and snow-covering upon the temperature of the earth, and are also compared with similar observations at Pavlovsk and St. Petersburg. The first regular observations of earth temperature in Finland were made at Sodankylä during the international polar expeditions of the years 1882-4; the present work, therefore, fills an important gap in the knowledge of the natural phenomena of that country, and will, no doubt, repay the large amount of careful labour bestowed upon it.

PROF. W. H. JULIUS has devised a very neat apparatus for eliminating all small movements due to vibrations from delicate instruments, such as galvanometers, &c. Last year (in the *Wied. Ann.*, 56, p. 151) he described this method, and a note on the subject was made in these columns (NATURE, vol. liii. p. 578). Quite recently he has given an account of a modified form of apparatus into which instruments to be shielded from these vibrations can be placed. This apparatus consists practically of a kind of framework, suspended by three wire cords, into which the instrument to be used is placed. It is found that, under these conditions, vibrations which otherwise would have disturbed the instrument are nearly eliminated. There are, however, certain conditions to be fulfilled to reduce such vibrations to a minimum; for instance, it is advisable so to arrange the centre of gravity of the whole apparatus, with the instrument included, that this point should fall in the plane in which the three lower extremities of the wires are connected to the framework. Further, if there be any special point in the instrument in question which must be shielded from any influence or vibration—such as, for instance, the quartz or silk thread of a galvanometer—this point should also be brought into the same plane. The apparatus which Prof. Julius has devised is arranged to fulfil these requirements. It consists of three rods placed parallel to one another in triangular form, and coupled together at their extremities by two metal hoops. This framework is suspended by three metal wires, the latter extremities of which are fixed to it at three points near their middle parts, lying in a plane between two hoops, referred to above; a third hoop is placed which can slide lengthways along the three rods. It is on this that the instrument to be freed from vibrations is placed. To bring the whole centre of gravity to a point in the plane of the three points of suspension, the framework is suspended horizontally temporarily by one of the wires; and the balance of the apparatus, with the instrument attached, is obtained by varying the position of the three weights placed near the ends of the rods for that purpose. The adjustment of that special part of the instrument which must be freed from vibration, is made by placing this, as near as possible, at the centre of gravity. To deaden any movements in the whole apparatus, three fan-shaped appendages are fixed to the hooks to which the wires are attached, and these are intended to be immersed in vessels filled with paraffin. The apparatus itself seems, from all accounts, to overcome the difficulties occasionally met in freeing delicate instruments from minute tremors. After being once accurately suspended, the chief difficulty in its adjustment is practically at an end. Supplied with the apparatus is also a small bracket, which can be fixed to the ceiling or beam, from which the apparatus can be suspended.

MR. G. C. WHIPPLE reprints from the *Technology Quarterly* (Boston, U.S.A.) an interesting paper on the growth of diatoms, especially in relation to the purity or impurity of drinking water. An abundant food supply is not the only favourable condition for the rapid increase of diatoms; temperature, the amount of light, and other conditions also influence their growth. In common with other chlorophyllaceous plants, they will not grow in the dark; while, on the other hand, bright sunlight kills them. The intensity of the light below the surface of the water being influenced by the colour of the water, diatoms are found most abundantly in light-coloured waters. Different genera, however, present differences in this respect; *Melosira* does not require so much light as *Synedra*. The weather has a marked influence on their growth. They increase most rapidly during those seasons of the year when the water is in circulation throughout the vertical. During these periods, not only is food material more abundant; the vertical currents keep the diatoms near the surface, where there is light enough to stimulate their growth, and where there is abundance of air. Some species of diatom display very strong heliotropism, moving towards the source of light.

THE two latest additions to the Encyclopédie Scientifique des Aide-Mémoire are:—"Les Accumulateurs électriques," by F. Loppé, and "L'Éclairage: Éclairage électrique," by Prof. J. Lefèvre. The volumes set forth clearly and well the principles which have their applications in those branches of electrical engineering expressed by the titles.

AT the Royal Victoria Hall on December 1, Dr. W. D. Halliburton, F.R.S., will lecture on "Painlessness," in commemoration of the jubilee of the discovery of anæsthetics; and on December 8, Dr. W. F. Hume will take "From the Crimea to Baku" as the subject of a discourse. A few months ago (vol. liv. p. 232) Dr. Hume contributed an account of the great oil region of Baku to these columns.

THE experiments of M. H. Bazin "upon the contraction of the liquid vein issuing from an orifice, and upon the distribution of the velocities within it," clearly advanced the knowledge of the important and difficult question of the liquid vein. The memoir, in which the investigation was described, has been translated by Mr. John C. Trautwine, and published by Messrs. John Wiley and Sons. Hydraulic engineers and mathematical physicists will be glad to have this authorised translation in a handy volume form.

MR. W. DOBERCK, the Director of Hongkong Observatory, has sent us a copy of his report on the work done during 1895. All the typhoons—about 250—observed since the observatory was established in 1884, have now been investigated, and Mr. Figg, in conjunction with Mr. Doberck, is at present engaged

in studying the laws of storms on the basis of these investigations. Meteorological observations are made at the Treaty Ports and transmitted to the observatory, and the hope is entertained that the number of ports from which such information is telegraphed will be greatly extended; for there is no meteorological service in China, and the data at present collected is insufficient.

THE Manchester Literary and Philosophical Society was founded so long ago as February 28, 1781, the number of original members being twenty-four. Some interest, therefore, attaches to the complete list, just issued, of the members and officers from the institution of the Society to April of this year. In the same publication are bibliographical lists of the manuscript volumes dealing with the affairs of the Society, and of the volumes of the *Memoirs* and *Proceedings* issued by the Society. There are also two appendices setting forth the original rules adopted and the objects of the meetings.

IN looking through the *Transactions* lately received from three local scientific societies, the fact is brought to mind that practically all such societies are concerned with natural history, scarcely any attention being paid to physical science. In the *Transactions* of the Leicester Literary and Philosophical Society are papers on bacteria and their importance in nature, Coleoptera of Bradgate Park, and insects in relation to the fertilisation of flowers. The Natural History *Transactions* of Northumberland, Durham, and Newcastle-upon-Tyne—the publication of the Tyne-Side Naturalists' Field Club, founded fifty years ago—contains papers on Entomostraca collected in the Solway district and at Seaton Sluice, Northumberland, during 1894, a catalogue of the spiders of Northumberland and Durham, and the results of a systematic study of pollen. In the *Transactions* of the Norfolk and Norwich Naturalists' Society are several really valuable papers. The President, Mr. H. D. Geldart, devotes his address to the consideration of the distribution of flowering plants in the Arctic regions, and strives to show that the commonly accepted hypothesis of the migration to and fro of the Arctic flora with the greater or less intensity of cold is not consistent with facts, but that plants have held their own in their old localities in spite of the intense glaciation to which they have been subjected. Mr. Geldart is also associated with Colonel Feilden in two interesting papers on Arctic Botany. Among other papers are some instructive notes on the Flora of Great Yarmouth and its neighbourhood, by Mr. G. B. Harris; and Mr. Stacy Watson contributes an account of the herring fishery from that port and Lowestoft. Some observations on the rare New Zealand Owl, *Sceloglaux albifaces*, in captivity, with a figure, are contributed by Mr. J. H. Gurney, and Prof. Newton follows with a note on an early record of the breeding of the Spoonbill in Norfolk; while Mr. Miller Christy notes a reference to an occurrence of a Narwhal in the same county in the year 1588. A list of the Mollusca of Norfolk is given by Mr. Mayfield; Mr. Preston continues his long series of Meteorological Notes for the neighbourhood of Norwich; and Mr. Southwell describes interesting recent additions to the Norwich Castle Museum.

THE *Journal of the Asiatic Society of Bengal* (vol. lxv. part 2, p. 66) contains an investigation of the decomposition of aqueous olutions of sodium hypochlorite at the temperature of boiling water, by Jyotibhushan Bhaduri. It is of interest that solutions containing from 1·5 to 1·7 per cent. of the hypochlorite, decompose less rapidly than those of any other concentration. The decomposition results in the formation not only of sodium chlorate, but also of considerable quantities of free oxygen.

IN the current number of the *Comptes rendus* M. A. Leduc gives an account of some further experiments on the densities of oxygen and nitrogen, the repetition of the determinations o the latter being necessitated by the discovery of argon. The nitrogen was prepared from four distinct sources (ammonium nitrate, ammonium nitrite, nitric oxide, and ammonia), every possible precaution being taken to ensure the purity of the gas. For the flask employed, all the weights of nitrogen found fell between 2·8467 grams and 2·8474 grams, the mean result corresponding to a relative density of 0·9671 (air = 1). The experiments with the oxygen obtained by the electrolysis of potash solution were also repeated, greater precautions being taken to remove all traces of hydrogen, while, in a second set of experiments, oxygen obtained by the action of heat upon potassium permanganate was employed, the mean relative density being 1·10523, a slight increase on the earlier results. By taking the values found for the densities of chemical and atmospheric nitrogen, together with the results of M. Schloesing, jun., on the ratio of argon to nitrogen in atmospheric nitrogen, the value 19·8 is found for the density of argon compared with hydrogen. The close agreement between this and the value found directly (19·94), affords a useful check upon the results.

THE additions to the Zoological Society's Gardens during the past week include a Sykes's Monkey (*Cercopithecus albigularis*, ♂) from West Africa, presented by Mrs. Gooding; a Squirrel Monkey (*Chrysothrix sciurea*) from Guiana, presented by Mr. James W. Wells; a White-fronted Lemur (*Lemur albifrons*) from Madagascar, presented by Mr. Richard A. Todd; a Red-bellied Squirrel (*Sciurus variegatus*) from Mexico, presented by Mr. James Meldrum; a Vulpine Phalanger (*Trichosurus vulpecula*) from Australia, presented by Mr. George Turner; two Brown Mynahs (*Acridotheres fuscus*) from India, presented by Mr. H. Nowell; a Mute Swan (*Cygnus olor*), British, presented by Mr. J. Culling; a Hawk's-billed Turtle (*Chelone imbricata*) from tropical seas, deposited.

OUR ASTRONOMICAL COLUMN.

STARS WITH PECULIAR SPECTRA.—A recent examination of some of the Draper Memorial photographs, by Mrs. Fleming, has resulted in finding some interesting cases of peculiar spectra (*Harvard College Circular*, No. 12). The spectrum of − 39°3939 is described as very remarkable, and unlike any other as yet obtained. Three systems of lines cross the continuous spectrum. First the dark hydrogen lines and K, then two bright bands or lines at approximate wave-lengths 4652 and 4698. A third series has for the wave-lengths of its lines 3814, 3857, 3923, 4028, 4203, and 4505, the last being faint. These latter six lines form a rhythmical series similar to that of hydrogen, and "apparently are due to some element not yet found in other stars or on the earth." Balmer's formula was not capable of representing this series, but a modification of it gave the wave-lengths of the lines as 3812, 3858, 3928, 4031, 4199, and 4504. The only other line found in the spectrum was 4620, being apparently independent of the series just mentioned. The star R.A. (1900) 12h. 26·9m. Decl. − 57° 1′ is a new variable in Crux. Its period is about a year, and its photographic magnitude is deduced as being 10·3 at maximum, and fainter than 13·2 at minimum N.G.C. 6302 was found on July 9, 1896, to contain the bright lines characteristic of gaseous nebulæ. The stars designated +44°3649 and +44°3679 have similar spectra, containing two bright bands "resembling, and perhaps identical with, those in the spectrum of ζ Puppis." Miss Louisa D. Wells has found a new variable in Cygnus, its approximate position for 1900 being R.A. 21h. 38·8m., Decl. +43° 8′. It has a period of about forty days, and fluctuates between 7·2 and 11·2 photographic magnitudes. This range is somewhat considerable for such a short period variable.

THE LEONIDS.—From the account of the Leonid meteors given in the last number of NATURE, it would have been gathered that the shower was after all only a very ordinary one, the time of maximum being estimated as having occurred during the early part of the night of the 14th. An observer, who has written to the *Dumfries and Galloway Courier and Herald*

(November 18), seems, however, to indicate that the morning of the 15th was far richer in meteors, as the following extract indicates: "At that hour (Sunday, 3 a.m.), however, we looked out, and finding that a few stars were 'on the shoot,' began to watch for them. Till well after four o'clock there were not many visible; something like one every two or three minutes. By five o'clock they markedly increased, and from 5.15 to 5.45 there was quite a shower, and between these times we counted over sixty meteors. Once three 'came away' almost simultaneously, and another time two flashed out together. Nearly all of them were very small, and had very short and very swift flight, and many were scarcely more than just visible. There was one brilliant exception that shot out from the feet of the Twins, and disappeared near Orion's belt, that was of first magnitude, and left a red streak that remained for twelve or fifteen seconds afterwards. At six o'clock the meteors seemed almost suddenly to cease, and shortly afterwards our vigil came to an end."

M. PERROTIN, director of M. Bischoffsheim's private observatory at Nice, has resigned his post in order to become an observer at the Meudon Astro-physical Observatory.

MR. BALFOUR ON SCIENCE AND INDUSTRY.

MR. ARTHUR BALFOUR was the principal guest at the Cutlers' Feast at Sheffield last Thursday evening. In the course of his reply to the toast "Her Majesty's Ministers" he referred to scientific education in Germany, and the relations between science and manufacture. It is satisfactory to know that these subjects are now occupying the minds of our political leaders, and that such sound views should be expressed on the value of scientific research, and the true meaning of technical education, as those contained in the subjoined *Times'* report of Mr. Balfour's speech:—

"I think that, though we have not much to fear from the action of other nations, we have much to learn from the action of other nations. I have already said that I think John Bull requires the occasional stimulus of a panic to make him do his best. He is like a noble horse dragging a load, well within his weight, who perhaps gets a little slow in his action unless occasionally he hears the crack of the whip. I think that, though I do not envy the growth of German manufactures—taking Germany for example—though I neither envy the growth of German manufactures, nor fear the growth of German manufactures, though I do not think that German prosperity can be other than in the long run a help to British prosperity, still I am not so blind as to think, with regard to a nation which gives itself over with such fervour to everything which can by discipline and education promote its material prosperity, that we have nothing to learn by the study of its proceedings. I believe we have a good deal to learn, and I think it behoves us to learn it. Lord Rosebery desired that an inquiry should be made into the topics on which I am venturing to arrest your attention to-night. That inquiry is being made, or is partly being made, by the department of the Government concerned. I do not profess to give the results of these inquiries, but it is an undoubted fact that the Germans do think it, rightly or wrongly, to be worth while to spend money Imperially, municipally, and privately upon those branches of scientific research which have a direct bearing upon manufactures to an extent and degree absolutely unknown in this country, which surely ought to take the lead in all commercial matters. I have been informed by a gentleman who has recently come from an examination of these technical institutions in Germany that there are at this moment in Germany no fewer than six great technical institutions for the study of electrical matters alone, which are superior to anything of the kind which we have in this country. The witness of whom I speak was not a prejudiced witness. He went to Germany with no preconceived views either for or against the method of technical instruction there pursued, and I have faithfully detailed to you the information I gained. I am further informed, on evidence the value of which I cannot for a moment doubt, that, while the Government and the municipalities spend these vast sums in producing a great body of trained experts, the great manufacturers in Germany, to an extent altogether unknown in this country, employ a large body of investigators on their own account on their own premises, taking advantage of every discovery that can be made, and in so far as may be make discoveries for themselves. I do not comment upon the fact; I simply state the fact to you. I should be reluctant to say how great is the advantage which any country thus liberally disposed is likely to reap. It may be that the Germans have been squandering their money in unremunerative investigation, and that they will not get in the shape of national profit any result for what they have done. That may be so, but I remember the late Mr. Bagehot's pointing out that one of the great advantages that England had over every other nation in the world was this—that when any discovery was made, when any new outlet of industry was invented, the amount of disposable English capital was so great that England reaped the chief benefit from it. Now this is the question I want to put. Is not Germany, by bringing into existence this vast body of fine specialists, preparing itself to make the utmost use of any possible advances in scientific manufactures which may be made? Is it not likely that it will have the advantage, as compared with other nations, in turning to account the smallest hint in any direction, in developing any discovery however slight, in making the most of any advance, however small that advance may be? That question I put to men incomparably more qualified to answer it than I am myself."

"But I think the question is worth putting in the great manufacturing centres of this country, and I would ask them not to be put off—I do not think Sheffield is likely to be put off—but I will ask any who read my words not to be put off with the idea that what is called technical instruction, by which I mean manual instruction in arts and crafts, however good in itself, has anything to do with the particular kind of education of which I am speaking. It has nothing to do with it. Education in the first three standards of your primary schools has more to do with the higher University training than the manual education of which I speak has to do with the technical education which I desire for the country. For the education in your primary schools is, after all, a necessary preliminary of your University education. You must learn to read, you must learn to write, you must learn to do arithmetic before you can take advantage of what Oxford and Cambridge, Edinburgh and Glasgow, have to give you, but still education in the three R's leads up to all this knowledge, but the manual education called technical does not lead up to and has no relation to or connection whatever with that scientific education of which I speak. England became a great manufacturing country, the greatest manufacturing country which the world has ever seen, before the intimate relation of organised science to manufactures was thoroughly understood. I fear that in some quarters it may still be a fact that the relation between science and manufactures is not thoroughly grasped, and there may still be some who think that money spent in what appears to be abstract investigations far removed from the practical things of life has but a small effect on national well-being and national commerce. If any hold that view, believe me, they are profoundly mistaken. They have not followed the course of human knowledge, they have not kept abreast of human progress, and if we have leeway to make up in this matter, if we have to learn a lesson which perhaps came easier to the Germans than it did to us, let us hasten, at all events, to learn that lesson completely, and then I doubt not we shall—even in the eyes of the most pessimistic critic—continue to hold that position which hitherto we have held unchallenged, and then British manufactures, British industry, British capital may still maintain throughout the world the supremacy they have so long held and so well deserved."

THE LONG PERIOD WEATHER FORECASTS OF INDIA.

IN days when the *cui bono* of everything connected with scientific research is subjected to the glare of criticism by a public which is frequently too busy to analyse or understand the laborious methods by which accurate knowledge is attained, the Meteorological Service of India poses as a happy exception to that of many other scientific departments in being able to demonstrate its practical utility by the success, not merely of its every-day routine forecasts, but by its unique initiation and development of seasonal or long-period forecasts of the alternate monsoons.

The foundations so carefully laid by the late Mr. Blanford, have enabled his successor, Mr. Eliot, to realise the expectations he so hopefully expressed years ago regarding the important *rôle* that India would play in the future development of meteorology.

Beginning with a few empirical sequences first suggested by Blanford, the principles on which the seasonal forecasts, issued semi-annually from the Simla Office, are now based, are every year becoming more rational and trustworthy, and recognising the immense practical service of such a system to the country, the Government have recently sanctioned the establishment of fresh observing stations in Persia, a cable to the Seychelles, and the continuation of the monsoonal charts of the Indian Ocean, which have already thrown considerable fresh light upon the conditions which regulate the normal and abnormal development of the weather characteristics of each monsoon in different years.

The exceptional feature possessed by India, in common with most tropical countries, and which renders it possible to deal with its weather in broad masses and for long periods, instead of by the hour or day, is the fact that the periodic or climatic changes are far more important than those irregular, aperiodic, and ephemeral fluctuations which in these latitudes constitute the dominant components of weather.

Thus, to quote a single example, when all the extreme diurnal changes of pressure at principal observatories in India are tabulated for a year in groups according to magnitude, it is found that 95 per cent. of them are less than those which are due to the regular hourly oscillation; and the same is true of similar changes in the other elements.

In brief, while daily weather anomalies and their prediction are the chief problem of the European forecaster, the relative unimportance of these in India, compared with the broad seasonal changes, or the variations of the average weather of a season from the normal (where each day resembles its predecessor so much that the effects of a certain type become cumulative, instead of being compensated by alternation), naturally leads the Indian forecaster to regard the elucidation of long-period variations, and their prediction, as the problem which should demand his principal attention.

Daily storm warnings may be of service to the shipping in the Indian ports, and round the coasts; but for everything relating to agriculture and internal land economy, seasonal forecasts are undeniably superior.

With a good telegraphic system, daily forecasting can proceed fairly successfully on purely empirical lines, not unlike those by which a railway signaller is able to announce the arrival of an approaching train. On the other hand, successful prediction of circumstances not already in progress, and dependent upon conditions related to the movements of large air currents over extensive areas, and occupying considerable periods of time—if at first provisionally approached by empirical sequences—will ultimately necessitate as much rational inquiry, explanation and deduction as science alone can supply. India thus demands, and, fortunately, has hitherto succeeded in securing, a service of forecasters possessed of higher scientific training, as well as practical skill, than probably any weather service in the world.

The preparation of the monsoon forecasts in India is based at present on three or four broad sequences, whose rational causes are as yet only partially understood. Coupled with these are a considerable amount of deduction from rational hypothesis, comparison with present and past conditions over surrounding areas, analogy with like conditions in previous years, and modification according to ascertained persistence of local anomalies.

The determining factors may be classed as (1) local, (2) general. The local factors, which were formerly considered the most important and, indeed, the dominant causes of the monsoon, have, of late years, and especially since the publication of Indian Ocean monsoon maps, been shown to be subordinate to, and of merely secondary importance compared with, those which evidently control the strength and quality of the monsoon current itself.

For the summer, or south-west monsoon, these local factors are:—

(*a*) The snowfall of the preceding cold weather, and (*b*) the local anomalies over India and adjacent seas during the ante-monsoon months shown in the monthly average anomaly maps. At one time the former of these was thought to be the key to the problem of drought or heavy rains over the whole country during the ensuing months, scanty rains being the sequel to heavy snow. Experience, however, has shown that, while heavy snowfall over the Himalaya, especially late in the season, as in April and May, exercises an important influence in delaying the arrival, and checking the advance, of the monsoon over those areas of Upper India which border on the hills where such excessive falls have occurred, the converse is not so effective, while in any case the effects are liable to be counteracted by the intrusion over India of a monsoon current of more than ordinary strength. This latter is a circumstance which is regulated by influences connected with the circulatory system of the whole depth of atmosphere over an entire hemisphere, and, therefore, quite too large to be seriously modified by the local reactionary effects of a comparatively small snow-covered area.

Nevertheless, the reports of the winter snow-fall over the Himalaya are of considerable importance in estimating the complex probability of an early or late, favourable or unfavourable monsoon, and form one of the recognised official principles on which the final forecast is based in May.

The second factor (*b*), once thought to be all-powerful, and still of considerable importance in determining the average local and provincial variations of rainfall and weather during the prevalence of the monsoon, is estimated by the synoptic presentment of the temperature, and particularly the pressure anomalies exhibited in the monthly anomaly maps during the ante-monsoon or "hot-weather" period.

These anomalies are found to persist more or less throughout the entire period of the south-west monsoon, and indicate the lines or zones which are favoured or avoided by the cyclonic vortices which distribute the monsoon rains. As Mr. Blanford pointed out, in his classical memoir on the rainfall of India, they "rather indicate a dependence of the storm track on a quasi-persistent distribution of pressure than merely a modification of the average pressure distribution by the passage of the barometric depression accompanying the storm."

In fact they may be compared to the moulds into which molten metal is run, and which fashion its shape by guiding it into pre-existing channels and cavities.

The circumstances which determine the sudden bursting of the Indian monsoon in the first week of June, have recently been graphically described by Mr. Eliot in his paper on the character of the air movement on the Indian seas and equatorial belt during the south-west monsoon period, in the *Quarterly Journal of the Royal Meteorological Society* in January of the present year.

From a careful study of the Indian monsoon charts, and the barometric conditions over the equatorial region, it has been found that the northward advance of the sun, and the establishment of a thermal focus over the Indian land area, tends to weaken the northern side of the equatorial atmospheric crater which surrounds the ascensional terminus of the normal north- and south-east trade-wind systems, and finally stop the ascensional outlet for the latter. Its consequent horizontal outflow northwards, like a pent-up lava stream, towards the newly-formed ascensional focus over the Indian land area, occurs during the last fortnight of May, in conjunction with a simultaneously sudden rise of pressure over the equator, and a consequent increase in the northward gradient.

This sudden transformation is, moreover, effected apparently more by actions tending to increase the high pressure south of the equator, due to the seasonal enlargement of the permanent south polar cyclone, than by any local actions over India or Southern Asia, though it is possible that the general conditions over the latter assist.

It is, therefore, to the South Indian oceanic area that the attention of the Indian forecasters of the monsoon is now directed, in order that they may have early intimation of the variations in the "*vis a tergo*."

As soon as the current reaches the Indian land area, it fills up the local inequalities in the pressure mould; and since by the principle of "courant ascendant" persistence, such local characteristics, once initiated, tend to continue, the forecaster is able to deduce, on the supposition of a normal, excessive, or weak monsoon (a distinction which can ordinarily be determined on its first appearance), the probable local deviations which form such a valuable practical part of the forecast. The results of these two local factors, together with those of a more subordinate character, are all liable to serious modification through the dominant influence of

(2) The general character and strength of the monsoon current.

It is now one of the accepted canons of Indian meteorology, which may be considered as due to the industry and perspicacity of its present high priest, that while the antecedent local anomalies over the Indian area, introduced by thermal conditions, modify the character of the current and control its local effects, they are in no sense, as was formerly believed,

its proximate cause, and that the changes in its general strength and character from year to year are more the result of actions taking place south of the equator than of any peculiar conditions over the south Asiatic land area.

The extension of the area of observation, as far as Mauritius and the Seychelles, is the logical outcome of this principle; and though the information at present obtainable is mostly empirical in form, it is found that the essential subsequent unity of the south-east trade and the south-west monsoon enables early information of the character of the former in the southern seas to be used as an empirical index to the seasonal character of the latter as soon as continuity has been established across the equator.

A strong trade-wind argues *pari passu* a strong monsoon, and therefore a good rainy season over India, except where it is counteracted by opposing local factors.

It will probably be some time before rational knowledge of this important factor will supersede the empirical for the purposes of practical forecasting. Meanwhile every extension of the means of accelerating the transmission of news of south-east trade conditions is invaluable in forming a trustworthy seasonal forecast from the Simla Office.

The summer monsoon forecast is made up provisionally about the fourth week in May, and held over until symptoms of the coming monsoon manifest themselves in Bombay, in order to allow of the latest information being incorporated. June 6 or 7 is the average date for Bombay, and it is frequently from two to three weeks later before it reaches the Punjab.

The work of preparation is no light matter, since the greatest care is taken by Mr. Eliot to allow for every factor, and to arrive at a fair balance of probabilities.

It is a serious matter to forecast for six months over an area half as large as the United States, and the work occupies a week after every map and datum is on the table.

Two points on which the agricultural value of the monsoon rainfall largely depends are at present only partially predictable, viz.: (1) the probability of a prolonged break in the rains in July or August, and (2) the probability of an unusually early termination of the rains in Upper India or Bengal.

The former depends chiefly on the relative strength of the two branches of the monsoon current, the break generally occurring with a relatively weak Arabian Sea current, while the latter depends on the early establishment of the high pressure over North-west India and North Burmah, which causes the reversal of the gradient, and, as it were, drives the monsoon out of the Bay of Bengal.

These conditions can only be inferred months before their occurrence by analogy with previous years presenting similar characteristics.

Once they have started, however, they can be employed in determining the probability of the early or late occurrence of the rainfall of the winter monsoon.

The rainfall of this monsoon, though very inconsiderable compared with that of the summer, is, agriculturally speaking, of great value, since upon its presence the entire fortunes of the rabi crop depend.

Originating, as Mr. Eliot has so exhaustively shown in his recent "Memoir on the Winter Storms of India," in a lofty current 10,000 feet above sea-level, having no lower oceanic continuation, and shedding its vapour in storms bred on the plateaus of Afghanistan and Persia, it is at present impossible to obtain direct information of the character of the winter monsoon before its descent to the North Indian plains in December. A divining-rod has, however, been lately discovered, by which it may be inferred from the nature of the vertical pressure anomalies for the months immediately preceding December.

These anomalies represent the departure from the mean of the monthly mean pressure at stations near the foot of the hills, minus the corresponding departures at the mountain stations 7000 feet above. When the differences (plain minus hill stations) are positive, the inference is that the subsequent winter will be a dry and stormless one; if negative, precisely the reverse.

Since the character of the winter monsoon is found to be remarkably constant all through, probably because being an upper current it is unaffected by local and land influences, the forecast from this empirical sequence alone is found to be remarkably trustworthy.

There are some additional sequences, first indicated some years ago, which are useful in confirming the conclusions derived from the vertical anomalies, such as the probability of a light winter fall succeeding a light and early departing monsoon, and *vice versâ*. Such sequences are, however, really included under a more general law which, though at present empirical in form, appears likely to lead to a rational explanation of the chief yearly variations in both monsoons. This law is the outcome of a recent discussion, by Mr. Eliot, of certain oscillatory variations of pressure which are found to be common to the entire Indian oceanic and continental areas.

It has been found that the monthly mean barometric pressure of India is subject to a series of long-period waves of nearly equal amplitude, ranging up to as much as ·07 inch (which is up to drought-producing power in India), and varying from twelve to twenty-four months in length. Twelve of these occurred in the last twenty years.

They are found to occur completely reversed in phase at Mauritius, and are considered to represent the major fluctuations in the annual oscillatory flow of air to and from the South Indian Ocean and India, in the form of the monsoons, together with similar conditions involved in the corresponding return flow in the upper and lower atmosphere, according as it is summer or winter. They are likewise precisely opposite in phase to the vertical anomalies. In other words, these oscillations of pressure represent compensatory variations in the horizontal transfer of air across the equator, and in the vertical transfers at the northern and southern termini of the circulatory system, which are intimately bound up with the strength and character of the monsoons.

The principal maxima pressures usually occur about the vernal, and the principal minima about the autumnal equinox. Employed as an empirical sequence for forecasting, the rule may be stated thus.

In years when the sea-level pressure anomaly is such that the curve is a descending slope during the spring months, the conclusion is that the south-west monsoon will be one of excessive rainfall, and *vice versâ* when the slope is ascending, it will be comparatively dry. Conversely, the years of heavy winter rainfall during the north-east monsoon, tend to coincide with the maximum epochs of these pressure anomaly waves, *i.e.* with the minimum epochs of their vertical anomaly analogues, probably because diminished pressure above coincides with increased pressure below. *Vice versâ*, years of light rainfall coincide with the epochs of general minimum anomaly at sea-level. By the accumulation of such sequences, and their gradual determination in a rational form, the science of long-period forecasting is being built up in India

The occurrence of a severe scarcity during the present year is a timely commentary on the practical value and limits of the monsoon forecast.

Of the four causes detailed by Mr. Eliot in his paper on "Droughts and Famines in India," read before the Meteorological Congress at Chicago in 1893, the present famine is due to the last—viz. "Unusually early termination of the south-west monsoon rains. This is especially fatal in the case of rice crops on unirrigated land."

The same circumstance is also peculiarly prejudicial to the sowing of the winter or "rábi" grain crop which is reaped in March, especially when it is succeeded by scanty winter rains in December and January.

As has been already observed, this early termination of the south-west monsoon is one of the conditions which, at present, lies outside the conventional forecast, though it is rapidly becoming manifest that it is dependent on the general state of the south-east trade wind of the Indian Ocean. In the Foreçast Circular issued this year by Mr. Eliot, and dated Simla, June 3, attention is drawn to the fact that, during the past two or three years, the "causes of the large variations of the rainfall in India have been evidently due to abnormal conditions outside the Indian area, and not to local peculiarities or abnormal meteorological features in India itself."

The anomalies are so remarkable that they are worth reproducing, as in the following table.

Years.	Rainfall anomaly from normal over India in inches.	Percentage variation from mean.
1893 ...	+8·94	+22
1894 ...	+6·48	+16
1895 ...	−2·90	−7

The pre-monsoon conditions of temperature, pressure, and snowfall were almost identical in 1894 and 1895.

The south-east trade wind, however, was weak in 1895, and

the result was a deficient monsoon, which, moreover, terminated three weeks earlier than usual.

A similar weakness of the trades was visible, particularly at the Seychelles, this year. Hence, though Mr. Eliot was obliged to admit that the local conditions were favourable, he added a caution that "the inferences were to be accepted with greater reserve than usual."

The arena was ready for the gladiator if he arrived in good training, but the fight would depend on his strength. As events have shown, the gladiator monsoon was not "up to form," and the fight terminated a month earlier than usual all over Northern India and Burmah, with disastrous consequences to the kharif crop. It now remains to be seen whether the coming winter rains will be in defect or excess.

Until the end of the present month, when they can be inferred from the vertical anomalies of pressure, a provisional forecast can only be made on the law of sequences.

As a rule, "a light and early departing monsoon is followed by light winter rains." Consequently, so far, the outlook is serious. In such a case, however, by a similar law of sequence, the rainfall of next year's summer monsoon should be unusually heavy, so that the famine cannot continue for more than another six months. It is to be hoped that the omen may be averted, and that other factors may override the usual sequence and allow a good winter fall, which would, at all events, shorten the period of distress, and favourably modify, although it could not obviate the effects of the mischief done in September.

It would be impossible here to do more than cursorily advert to the moot question as to how far the periods of sunspot activity are directly related to the monsoons in a form in which they can be of practical utility in forecasting. *Pace* all that has been said to the contrary, there is no doubt that the condition of the sun introduces a long-period oscillation, probably of similar eleven-year period and small amplitude, into all the elements of Indian weather, modifying the epochal dates, and partially altering the character of the summer and winter rains; but year by year such a variation is too small, and too masked by others of larger amplitude, depending on changes of flow in the atmospheric currents of a less periodical and more rapid character, to admit of its entering as anything but a subordinate factor into the seasonal forecast. The attention of the department at present is so concentrated on these larger six-monthly and two-yearly oscillations, that it is unable to devote itself to the undoubtedly important task of determining the precise local value of the sunspot variation.

That this exists, however, even dominantly over the whole area, is plain from the following grouping of the yearly rainfall anomalies of the entire Indian area from 1864 to 1894, which shows that the total annual rainfall is slightly deficient about the epoch of sunspot minimum, and slightly excessive about the opposite epoch.

Groups of years.	Rainfall of India during the south-west monsoon. Anomaly from the mean smoothed figures.
Five years round year of minimum sunspot	− 0·40 in.
Five years round year of maximum sunspot	+ 2·10 ,,

The relation to the sunspots is, however, greatly modified according to locality, being especially marked during the south-west monsoon over the Carnatic and Ceylon, and occurring in a reversed phase during the winter rains of North India. Symptoms of an early arrival of the monsoon in years of maximum, and late in years of minimum, have been noted; but the general statistical examination of the question on a rational basis is still a desideratum, and one which, given the necessary additional staff, Mr. Eliot considers of sufficient importance to claim the attention of the department.

At present his view of the matter, so far as its value in practical forecasting is concerned, may be stated thus.

After all the other factors have been considered, the position of the year in the sunspot cycle may be taken as an index of the steadiness or variability of its general characteristics. Thus, in years of maximum sunspot the monsoon is distributed more evenly, and local anomalies are less exaggerated. The years about the epoch of minimum are characterised by greater local contrasts and irregularities. A comparison of anomaly ranges with sunspots would thus repay investigation, and they might yet be shown to possess a value far in excess of that indicated by the small fluctuations visible in the combined averages over dissimilar areas. DOUGLAS ARCHIBALD.

THE NEW RESEARCH LABORATORY OF THE ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.

IN 1888 the Royal College of Physicians of Edinburgh determined to establish and equip a laboratory for original research. The scheme was regarded by the College as to a certain extent experimental, and was proceeded with cautiously. Instead of erecting special premises, an old house in Lauriston Lane was rented, close to the Royal Infirmary, and this was adapted and equipped at an outlay of 1000*l*. The success of the scheme soon became assured, and a large number of workers availed themselves of the opportunities afforded by the new laboratory for conducting investigations. The chief results of their work are set forth in five volumes of Laboratory Reports, and a sixth is now in course of preparation. A very important function of the Institution, moreover, has been the issuing of reports on morbid specimens sent to the Superintendent by practitioners. This work has gradually increased. While in 1890 only fifty reports were sent out, last year no less than 417 specimens were examined and reported on. In addition to these two primary objects of the Institution, the preparation of antitoxin serums has lately been undertaken at the instruction of the College.

The original building soon proved inadequate for the growing work of the laboratory, and the College being assured that the influence of its laboratory tended to the maintenance of the scientific spirit in medicine, directed its Committee to seek for a site on which to place a permanent institution. After many failures the College succeeded in acquiring a site and premises adapted to their wants, which has been purchased and equipped at a cost of about 10,000*l*.

The new laboratory, which was opened on November 6, is situated in Forrest Road, in the immediate vicinity of the Royal Infirmary, the University, and other medical schools.

In equipping these new premises, the objects kept in view were:—

(1) To provide a research laboratory in which bacteriological, histological, and chemical and experimental physiological and pathological work might be carried on.

(2) To make provision for examining and reporting on specimens sent by medical men.

(3) To provide a photographic department for macro- and micro-photography.

(4) To make suitable provision for carrying on the preparation of curative antitoxins, &c.

The fitting-up of the laboratory is in every respect most complete. Those portions of the building intended for laboratory work are heated by hot-water pipes, and are lighted by electricity. Hot water and steam for heating water baths are supplied throughout the building from a high-pressure-boiler; and in each department the supply of gas and water can be shut off without interfering with work in the other parts of the laboratory. Communications between the various rooms is by interchangeable telephones. To the right of the entrance is a large, well-lighted apartment, which will be used as the general office of the laboratory and for the examination of specimens. Opening off this apartment are two photographic rooms, the outer of which contains the micro-photographic apparatus and an arc lamp in a lantern, while the inner is the dark-room. On the left side of the entrance hall access is obtained to the Superintendent's room and the experimental apartment, the principal room on the ground floor, which is fitted up with the most modern apparatus and appliances for the carrying on of experimental work. In the old laboratory the recording gear was driven by water-power; in the new premises this work is done by two small electric motors placed beneath the floor. On the first flat, to the left of the landing, is the chemical room and a smaller room fitted with fume chambers. Provided with a working bench with places for six workers, the general chemical room is equipped in the most modern style. A through draught for the fume chamber is secured by a small fan driven by an electric motor. On the left of the landing, again, are large and small histological rooms and several apartments forming the bacteriological department. One of these rooms will be used for the production of the media for growing germs, and the production of diphtheria antitoxin. This department includes an incubating room.

The new laboratory, like the old, is freely open to those who desire to undertake original investigations in the medical

sciences, on their giving evidence of being able to undertake such work with a good prospect of success. Applications are considered by the Committee, who recommend to the Council, and this body grants a place in the laboratory. Apparatus, chemicals, &c., are supplied by the College free of charge, while assistance is given by the Superintendent and a staff of laboratory servants.

The examination and reporting on morbid specimens was instituted primarily for the Fellows of the College, but in a really difficult case assistance is given to any medical man who may apply. While the preparation of antitoxic serum was undertaken for the Fellows of the College, any supply beyond that required by them will be available for other members of the profession.

A REPUTED MALAGASY MONKEY.

BY far the most important zoological event of the year, so far as mammals are concerned, is the discovery in the superficial deposits of Madagascar of certain remains of an extinct monkey-like animal. Of these remains—which include the imperfect front portion of a skull, and a considerable part of the lower jaw—an illustrated preliminary notice by Dr. C. J. Forsyth Major appears in the October number of the *Geological Magazine*. And although the author of that paper may modify some of his conclusions in a later and fuller communication, the discovery is too important to be passed over without mention in this journal.

The title of the paper—"Fossil Monkeys from Madagascar"—suggests the impression that all the conclusions and theories that have been published in regard to the origin of the Malagasy fauna will have to be amended or swept away. But a study of the figures and description of the specimen will show that this by no means follows. Without entering into structural details, it may be mentioned that the skull—so far as its imperfect condition admits of forming a conclusion—conforms in general features with the Anthropoid, as distinct from the Lemuroid, type; while the molar teeth are also monkey-like. In the upper jaw the dental formula is identical with that of the Neotropical *Cebidæ*—that is to say, there are three premolars. In the lower jaw there is also a similarity between the *Cebidæ*, the number of cheek-teeth being identical. But here the resemblance ceases, for the canine is absent, and its function is discharged by the anterior premolar, which is enlarged. In this respect, as in the number of cheek-teeth, the specimen resembles the typical *Lemuridæ*; but the front teeth are different, and the premolars are unlike those of either lemurs or monkeys.

In describing the fossil—under the name of *Nesopithecus*—the author states that it indicates a distinct family of the Anthropoidea, "intermediate in some respects between the South American *Cebidæ* and the Old World *Cercopithecidæ*, besides presenting characters of its own." He adds that the following general conclusions are suggested by the discovery: "(1) We may look forward in Continental Africa likewise for the discovery of Tertiary monkeys intermediate between *Cebidæ* and *Cercopithecidæ*. (2) The recent African *Cercopithecidæ* are not invaders from the north-east, as has been supposed; on the contrary, most, if not all, of the Tertiary monkeys of Europe and Asia are derived from the Ethiopian region. The home of a part, at least, of the Anthropoidea seems to have been in the southern hemisphere. This assumption is corroborated by the two facts—that Anthropoidea make their appearance suddenly for the first time in the later Tertiary of Europe and Asia, and that they are entirely absent from the Tertiary of North America."

To properly criticise these conclusions would require much more space than is allowed by the editor. It may be conceded, in the first place, that the specimen undoubtedly indicates a distinct family; whether, however, it is an Anthropoid, appears much more doubtful. The presence of a functional lower canine is so constant in that group, that I think it may be taken as a subordinal character. And in any case the functional disappearance of that tooth indicates that *Nesopithecus* is not an ancestral type of the existing Anthropoids. Whether the transference of the functions of the canine to the anterior premolar indicates any affinity with the Lemuroids, or is merely a case of parallelism, I am not prepared to say. But it does seem probable that the fossil is an offshoot from the original stock which connected the monkeys with the lemurs. And, so far as it goes, it tends to discountenance the view that the *Cebidæ* are not genetically connected with the old-world monkeys.

With regard to the other conclusions of Dr. Major, I believe there is good evidence of the occurrence of fossil monkeys in the French Phosphorites (although this has never been published); and it hence appears probable that the ancestors of *Nesopithecus* may have reached Ethiopia with the other progenitors of the Malagasy fauna. I would further hazard the suggestion that the ancestral South American *Cebidæ* likewise reached Ethiopia at the same time, and that they migrated to South America in the manner I have suggested in my recent volume on the Geography of Mammals for the Santa Crucian Ungulates. The supposition of Dr. Major that "most, if not all, of the Tertiary monkeys of Europe and Asia are derived from the Ethiopian region," does not appear to have sufficient evidence for its support. And if it were admitted, we should have to account for the absence of true monkeys in Madagascar. Probably the *Cercopithecidæ* and *Simiidæ* reached Ethiopia with its antelopes and zebras. Hence there seems no reason, at present, for modifying our conclusions as to the origin of the Malagasy fauna.

As it is a somewhat important matter, I may take this opportunity of asking—should this meet his eye—the German Professor who some years ago showed me at the British Museum some monkey-like molar teeth from the French Phosphorites, if he would either describe his specimens or communicate with me.

R. LYDEKKER.

MICROSCOPIC MARINE ORGANISMS IN THE SERVICE OF HYDROGRAPHY.

IT has for a long time been known that the sea abounds in microscopic organisms, both animal and vegetable. Among the former are entomostraca, infusoria, radiolarians, foraminifera, as well as larvæ of mollusca, radiates, and bryozoa. Among the plant-life the mass consists of diatoms, cilioflagellates, flagellates, and certain unicellular chlorophyllaceous algæ. For these pelagic forms Prof. Hensen has proposed the name *plankton*, which has been universally accepted.

Some years ago I examined the samples of vegetable plankton collected by the Swedish Arctic expeditions, as well as samples from various parts of the tropical seas, and I became convinced that certain parts of the oceans are characterised by different species. In the year 1893 I spent the summer at the west coast of Sweden, where I had the opportunity of examining the plankton at the marine biological station of Christineberg, that is to say in a fjord (loch) called Gullmarsfjord. I found that in the month of June the plankton consisted mainly of cilioflagellates, *Ceratium tripos* being the most common. During the last days of the month, however, the plankton changed. The water was from that time very rich in entomostraca, and the cilioflagellates became less abundant. At the same time the mackerel appeared in the fjord. All my samples had been collected at the mouth of the fjord, where the water is not very deep. In the interior the fjord becomes deeper, as is the case also with the Scotch lochs, and I now wished to know the character of the plankton at different depths. What I hitherto had examined was the plankton of the current, called by the Swedish hydrographers the Baltic current, which in the spring and summer runs along the Scandinavian coast up to Bergen, in Norway. Below that surface current there exists, according to the Swedish hydrographers, water with lower temperature and greater salinity. In company with Prof. G. Thél, and with the aid of his net, which could be closed and opened below the water, I made in July an attempt to get plankton from different depths of the fjord. We found in the cold bottom water very little plankton, some few specimens of a large *Sagitta* and of *Calanus finmarchicus* only. At about 30–40 metres the cilioflagellates (among them *Ceratium divergens*) were abundant, and on the surface the entomostraca. This examination was repeated during the first days of August, when I and Dr. Aurivillius had the opportunity of accompanying Prof. S. A. Pettersson and Mr. G. Ekman on the hydrographical expedition which went out at the time. The result was the same as before, but from the determination of the temperature and the salinity of the water it became clear that the plankton had been collected in water differing in those

respects, and consequently that the different strata of water were characterised by different amounts of plankton, and by different species. Samples of plankton were afterwards collected by the Swedish hydrographical expeditions, at the same time as samples of water for physical and chemical research. The examination of the plankton was carried out by Dr. Aurivillius, who took charge of the animal plankton, and by myself, who undertook the vegetable.

Having examined a large number of samples, I have lately found that the plankton of the Skagerack and Kattegat can be classed according to the prevailing species, and in this way I distinguished four types, namely: (1) *Tripos-plankton*, (2) *Didymus-plankton*, (3) *Tricho-plankton*, and (4) *Sira-plankton*.

(1) The *Tripos-plankton* is characterised by its scarcity in diatoms and its abundance in cilioflagellates and entomostraca, which give to the spirit, in which the samples are preserved, an orange or yellow colour, all the other kinds of plankton colouring it more or less deep green. Among the entomostraca, according to the publications of Dr. Aurivillius, *Paracalanus parvus*, *Pseudocalanus elongatus*, and *Evadne spinifera* are the most abundant. Among the cilioflagellates *Ceratium tripos*, with the variety *macroceros*, is the most common. *C. divergens*, *C. furca*, and *C. fusus* occur in less numbers. Diatoms are, as I have said, scarce, the most abundant being *Coscinodiscus concinnus* and *Rhizosolenia gracillima*. In winter and early spring the unicellular alga, *Halosphæra viridis* is found in abundance. This kind of plankton characterises the water of the Baltic current, and prevails in the summer in the Kattegat and Skagerack. The organisms consist chiefly of euryheline and eurythismic species, which can withstand the dilution of the salter North Sea water by the slightly saline Baltic water.

It seems very probable that this first type of plankton may by future researches be split up into different kinds. We may thus, perhaps, distinguish one kind, characterised by *Halosphæra viridis*, and occurring in the winter, another by *Rhizosolenia gracillima*, occurring in the summer, one with *Paracalanus parvus*, and another with *Pseudocalanus elongatus*, and so on.

In all cases it seems to be certain that the water containing this first type is derived from the North Sea as well as from the Baltic.

(2) The *Didymus-plankton* consists principally of diatoms, among which the most characteristic species are *Chætoceros curvisetus*, *Ch. didymus*, *Ditylum Brightwellii*, *Rhizosolenia alata*, and *gracillima* (the latter probably a residuum of Type 1), *Skeletonema costatum* and *Thalassiothrix Frauenfeldii* (the latter probably common to Type 3). A silicoflagellate, *Dictyocha speculum*, occurs constantly, but not abundantly. The cilioflagellates, as well as the entomostraca, are scarce.

This kind of plankton was predominant in the Skagerack and Kattegat in November 1893, filling the fjords from the bottom to the surface. With the water, containing this kind of plankton, the herring arrived on the shores of Scandinavia. It seems to have been a very large bulk of water that at this time set in to the coast, as it drove away the whole of the summer water from bottom to surface.

The diatoms of this type are not known from the Arctic Ocean or from the Northern Atlantic, but are well known from the coasts of France and Belgium and the English Channel. It seems thus to be beyond doubt that the water came from the southern North Sea, along the western coast of Denmark. The temperature, as well as the salinity, were found to be variable, but the plankton constant. In the Gullmarsfjord the water at the surface had a temperature of 7° C., at a depth of 30 m. nearly 12°, and at the bottom only 4° to 5°. The salinity amounted respectively to about 26–27, 32 and 33 to 37 per thousand. This variation may be explained by the mixture of the water of the second type with the water previously present in the Kattegat. Probably the warmest water was the most pure water of Type 2, and corresponds to one of the kinds of water called by the Swedish hydrographers the *bank-water*.

(3) The third type of plankton, the *Tricho-plankton*, is distinguished by its diatoms, especially the following species:—*Thalassiosira longissima*, *Rhizosolenia styliformis*, *Chætoceros atlanticus* (in a less degree also by *Ch. borealis* and its variety *Brightwellii*), and *Biddulphia mobilensis*. The first-named species occur abundantly and almost pure in the Northern Atlantic, south of Iceland; the last-named I observed at Plymouth, West Scotland, and in the North Sea. This plankton may thus be considered a Northern Atlantic plankton. At the Scandinavian coast it seems to occur very rarely in a pure state; in fact I have seen it only once, in February of this year, gathered at the bottom of the Christiana fjord (100 m.), where the temperature amounted to 7·5° C., and the salinity to 34·76 per thousand, the highest figures obtained by the hydrographical examinations of all the samples gathered in February 1896.

On the other hand, this plankton was frequently found mixed with the next type in samples collected at the time named.

(4) The fourth type, the *Sira-plankton*, consists also mainly of diatoms, but of different species, the most characteristic being *Thalassiosira Nordenskiöldii*, and *Th. gravida*, *Chætoceros grænlandicus*, *Ch. socialis*, *Ch. scolopendra*, *Ch. teres*, *Nitzschia seriata*, many of which belong to the Arctic seas, and some of which are new to science. Among the cilioflagellates the most abundant is a variety *arctica* of *Ceratium tripos*, distinguished by Dr. Aurivillius as a constituent of the plankton of Baffin's Bay.

There can be no doubt about the Arctic origin of this type. It occurred in the Skagerack and Kattegat this year in February and March, always more or less mixed with (3) and (1). In the Skagerack the water with Types (3) and (4) was covered by a shallow layer of water with Type (1); but in the Kattegat it reached the surface. The admixture of Type (3) shows that the water on or before its arrival at the coast of Sweden was mixed with Atlantic water. The temperature and the salinity were found to vary greatly, owing to the admixture of the slightly saline Baltic water, at this time of the year very cold.

I have observed the same type of water in some slides collected on the west coast of Scotland by Mr. George Murray, and sent to me by Mr. Grove. These samples had been gathered in the spring of 1888—a year remarkable in England as an unusually cold one.

As far as the plankton researches are advanced at present, we may conclude that the surface water around the Swedish coast consists in the summer of water from the North Sea mixed with Baltic water: that in the autumn its place is taken by water from the southern part of the North Sea, and in the winter by water from the Northern Atlantic and the Arctic Ocean. Whether these changes occur regularly every year, or in certain years only, cannot be answered for the moment. Probably the last change is in correspondence, as Prof. Pettersson has recently suggested, with variations in the amount of water which the Gulf Stream carries past Iceland, westwards to Davis Strait and eastwards to the Arctic Ocean.

I think I have proved by the above that the examination of plankton is a matter of the greatest interest, not only in relation to hydrography, but also to meteorology and to fishery questions. There can be no doubt about the close connection between the state of the sea and the movements of the air, and the still obscure causes of the migration of fishes may be found to be intimately connected with the change of water containing different kinds of plankton.

It is thus an important matter that the plankton of the North Sea should be thoroughly and systematically examined; but for this, international co-operation of all the nations around the North Sea is required. I imagine that a central station, under the direction of competent persons, and provided with adequate accommodation, might be erected. Samples could be collected at certain intervals, and by the same kind of apparatus at different stations, and sent to the central one for examination. The details should be published every month, and the general results formulated in a way that would be useful to hydrographers, meteorologists, &c. The marine biological stations already in existence will probably be found willing for co-operation in such an undertaking, but they will be able to collect plankton only near the shores or at short distances from them. For getting samples from the open seas, the officers of the steamers crossing the North Sea and the Northern Atlantic might be found willing to assist, as the plankton may, as Dr. John Murray hinted to me, be procured by pumping water into a silk net. I recently tried this method whilst crossing from Edinburgh to Göttenburg. I fastened the net to the pump when the deck was being washed, and in this way I obtained sufficient plankton to prove that in the last days of July the North Sea was almost free from diatoms, and its plankton consisted mainly of cilioflagellates and entomostraca.

P. T. CLEVE.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The Professor of Anthropology (Dr. E. B. Tylor) delivered a public lecture on Monday, November 23, at the Museum, on "North American Picture-Writing, with special reference to a Series of Historical Wampum-Belts of the Hurons."

The second meeting of the Junior Scientific Club for this term was held on November 18, and was very largely attended. Prof. Gotch performed an experiment showing the effect of a current induced in a nerve, insulated in air, by a Wimshurst electrical machine. Prof. Ray Lankester exhibited and described (1) a series of casts of the jaws and teeth of Ornithorhynchus, and of fossil mammalia from the Stonesfield slate; (2) a specimen of Triarthrus presented by Prof. O. C. Marsh; (3) a number of species of Leptocephali. In connection with the last, Prof. Lankester gave an account of the development of the eel as determined by Grassi. Lord Berkeley read a paper on "The Necessity of Metaphysics in Science," which was followed by a prolonged discussion.

CAMBRIDGE.—Mr. T. L. Heath, editor of Diophantus and Apollonius, has been approved for the degree of Doctor of Science.

The Council of the Senate propose to present a memorial to the Lord President of the Privy Council communicating the resolutions of the recent Conference on Secondary Education, and urging the importance of early legislation on the subject.

Mr. J. B. Lightfoot has generously presented to the engineering laboratory a refrigerating machine and ice-making apparatus especially adapted for experimental purposes.

Prof. Ewing, Prof. J. Perry, and Mr. J. B. Peace have been appointed examiners in mechanical science.

Mr. W. M. Fletcher and Mr. E. B. H. Wade have been elected Coutts Trotter students in experimental physics at Trinity College.

A BRILLIANT assembly met in the amphitheatre of the new Sorbonne on Thursday last, the occasion being the inauguration of the newly-constituted University of Paris. From the *Times*' report we learn that the magnificent hall was filled with a distinguished company, including the President of the Republic, the Prime Minister and his colleagues and the Presidents of the two Houses, the Academicians, the resplendent Diplomatic Corps, all the public bodies, the entire faculty of the Paris University in their robes, and some 5000 or 6000 students. The bodies hitherto forming part of the University of France, which now constitute the University of Paris, are the faculties of Letters, Sciences, Law, Medicine, and Protestant Theology. Without reckoning the 41 chairs of the Collège de France, which retains an independent position, the University has 116 professors, besides lecturers, laboratory directors, and experimentalists.

THE Report of the U.S. Commissioner of Education for the year ending June 30, 1894, consists of two volumes, each of more than one thousand pages. The mass of information thus brought together refers to schools of all grades and in all countries; but limits of space will only permit us to mention a few of the matters dealt with. The report of the "Committee of ten," appointed by the National Educational Association to inquire into the courses of study and conditions of secondary schools, was summarised in these columns a short time ago (vol. liv. p. 308). Another Committee, composed of fifteen members, was appointed to investigate, in a like manner, the work of elementary schools, and their report is included in one of the volumes before us. The Committee discussed in detail the several branches of study that have found a place in the curriculum of the elementary school, with a view to discover their educational value for developing and training the faculties of the mind. Language is given the first place, the opinion being that, in the form of reading, penmanship, and grammar, it should be prominent in the first eight years of study. Arithmetic is given the second place in importance of all studies, because it or mathematical study furnishes the first scientific key to the existence of bodies and their various motions. Mathematics in its pure form, as arithmetic, algebra, geometry, and the application of the analytical method, as well as mathematics applied to matter and force, or statics and dynamics, furnishes the peculiar study that gives the command of the quantitative aspect of nature. It is held that the study of arithmetic should begin with the second school year and end with the close of the sixth year, the seventh and eighth years being devoted to algebraical methods. Following arithmetic as the second study in importance among the branches that correlate man to nature is geography. This is, therefore, given the next place. The next study ranked in order of value by the Committee is history, after which come other branches, among which is science. It is held that "Natural science claims a place in the elementary school not so much as a disciplinary study, side by side with grammar, arithmetic, and history, as a training in habits of observation and in the use of the technique by which such sciences are expounded." Other matters of scientific interest dealt with in the report are forestry education in France; geology in the colleges and universities of the United States; rules for the spelling and pronunciation of chemical terms; rise and progress of manual training; American learned and educational societies, and criminology.

THE current number of the *Revue Générale des Sciences* contains a paper by M. Cornu, the President of the Académie des Sciences, on the objects of the instruction in the École Polytechnique, and on the principles which ought to decide the courses of instruction therein. In view of the multitudinous discussions in this country on the general questions of the co-ordination of the teaching in schools of different grades and of the prevention of overlapping, this paper is of exceptional interest. The general conclusions at which M. Cornu arrives are as follows. (We must refer our readers to the *Revue* for the arguments which lead up to them.) The object of the school is to give young men destined for the public services that theoretical knowledge which is necessary to enable them to perform their duties with confidence, and to qualify them to help towards the perfection of these services. What is termed *la Mechanique rationnelle* is the foundation of this polytechnic instruction. Students ought to be competent, at the end of their studies, to solve any problem which they may be called upon to deal with in their future careers of engineers and officers. Considering the limited number of years of study and the impossibility of any great development in the interesting subsidiary branches of science, the instruction in other sciences—such as analysis, physics, astronomy—ought to be arranged in such a manner as to assist in the completion and illustration of this course of mechanics. The list of acquirements demanded on admission ought to form a homogeneous whole, without either adventitious additions or serious omissions, capable of immediate application, and, as far as possible, easy of later completion, either by the courses of this school, or of the places of higher instruction, or even by the efforts of the students individually. The experience of old students and their teachers has shown that those subjects studied during the years preparatory to admission leave the most lasting impression on the minds of the students. The courses of the school leave a profound impression, it is true, but to a less degree than this preparatory work. Finally, since the preparatory instruction to the polytechnic school exercises this decisive influence on the minds of the students, it ought to be directed with a view to giving results which would form an intellectual equipment sufficient to serve during the whole career of the student. These results ought to be established by simple and general methods, and to be presented under a definite form on the same lines as those which will be used later. Not only should all useless refinements be carefully avoided, but even subjects which are not in immediate harmony with the general trend of polytechnic instruction.

SCIENTIFIC SERIALS.

American Journal of Science, November.—Missourite, a new leucite rock from the Highwood Mountains of Montana, by W. H. Weed and L. V. Pirsson. This new rock type forms a stock of granular rock intrusion in cretaceous shales, and in the fragmental volcanic material which overlies them, both being highly altered near the contact with the igneous mass. It is dark grey, coarsely and evenly granular, and on closer inspection presents a mottled appearance. The minerals present are apatite, iron ore, olivine, augite, biotite, leucite, and some zeolitic products. This is the first granular volcanic rock in which leucite has been found.—Viscosity of mixtures of liquids, by C. E. Linebarger. The viscosities found by Ostwald's method are all less than those calculated by the rule of mixtures, except in certain mixtures of benzene and chloro-

form, and of benzene and carbon bisulphide. In the latter the differences are very slight, and these liquids may be said to preserve their viscosities without appreciable change. But when the constituent liquids have very different viscosities, such as benzene and nitro-benzene, the resultant viscosity is lowered considerably.—Volume measurement of an air thermometer bulb, by W. G. Cady. This may be accomplished without filling the bulb with water or mercury, by connecting it with a short graduated tube, changing the volume of the combination by an amount indicated on the graduations, and measuring the increase of pressure.—Residual viscosity and thermal expansion, by H. D. Day. A bar of vulcanised rubber expanded until 50° was reached, and then suddenly contracted. On again heating after some time, it expanded till it reached the highest temperature at which it had been maintained beforehand, and then contracted again. This phenomenon is due to internal strain in its manufactured state, and to a consequent molecular settling which sets in at certain temperatures.—Application of certain organic acids to the estimation of vanadium, by P. E. Browning and R. J. Goodman. Describes the determination of vanadium by means of tartaric, oxalic, or citric acid in the presence of molybdenum and tungsten.—Determination of oxygen in air and in aqueous solutions, by D. A. Kreider. A known volume of air is conducted through a strong solution of hydriodic acid in the presence of nitric oxide; the acid is neutralised by potassium bicarbonate; and the liberated iodine is titrated with standard decinormal arsenic solution, from which the equivalent volume of oxygen is readily calculated.—Amphibian footprints from the Devonian, by O. C. Marsh. A genuine specimen of a footprint from some vertebrate animal, apparently amphibian, has been found in the Upper Devonian of Pleasant, Warren County, Pennsylvania. This is the first evidence of life superior to the fishes found in that formation. The specimen is preserved in the Yale Museum.

Wiedemann's Annalen der Physik und Chemie, No. 11.—Rotations in a constant electric field, by G. Quincke. Rods, plates, spheres, or cylinders of a dielectric substance, suspended in a liquid dielectric between vertical condenser plates, exhibit slow rotations about an axis parallel or at right angles to the lines of force when a constant field of sufficient intensity is maintained between the plates. The author describes a great variety of experiments which exhibit this curious phenomenon. He explains it by the electrostatic deformation of the air film adhering to the bodies and producing a tangential pressure.—Photo-electric residual action of kathode rays, by J. Elster and H. Geitel. Alkaline chlorides exposed to the action of kathode rays assume peculiar colorations, and become photo-electrically sensitive. At the same time their phosphorescence diminishes, and a bluish film resembling an alkali metal is deposited on the walls of the tube. The authors naturally supposed that this consisted of metallic sodium, potassium, cæsium, or rubidium due to decomposition of their respective salts by the kathode rays. This would account for the observed photo-electric behaviour. But mercury was incapable of forming an amalgam with the deposit, and this explanation is therefore excluded. That it must be sought in a modification of the salt itself is shown by the fact of the photo-electric property remaining in the open air as long as the colour remains. Similar properties are possessed by colourless fluorspar, by potassium carbonate and glass, and to a slighter extent by calcium and barium chlorides. The authors think that a slight reduction takes place, and that the metal produced forms a solid solution in the remainder of the salt.—Interference refractometer for electric waves, by O. Wiedeburg. Describes an arrangement corresponding to Jamin's refractometer adapted to electric waves. The refractive index of paraffin found by this method is 1·418, and of plate glass 2·63, with a probable error of only 1 per cent.—Helmholtz's absolute electro-dynamometer and its use in determining the E.M.F. of a Clark cell, by K. Kahle. The electro-dynamometer consists of a square metallic band acting upon a coil attached to the arm of a balance, the planes of the band and the coil being perpendicular to each other. The square shape has the advantage that only its corners need support, and the band allows of strong currents and simplifies calculation. The E.M.F. of the H-shaped Clark cell was found to be 1·4488 volts at 0° and 1·4322 at 15°.—The cadmium standard cell, by W. Jaeger and R. Wachsmuth. A Clark cell of the H-shape, in which cadmium amalgam is substituted for the zinc amalgam and cadmium sulphate for zinc sulphate has an E.M.F. of 1·019 volts at 20°. It has an extremely small temperature coefficient (0·004 per cent., instead of 0·1 per cent. as in the Clark cell), and it is not surpassed by the ordinary Clark cell as regards durability and facility of reproduction.—Influence of Röntgen rays upon the steam jet, by F. Richarz. Since X-rays make air temporarily conducting, and therefore probably lead to ionic dissociation, they would also on that account increase the condensation in a steam jet. This is actually the case, as the author showed by exposing a steam jet, screened from direct electrostatic action, to the rays traversing an aluminium window.—Aluminium amalgam, by V. Biernacki. This may easily be obtained by dipping an aluminium wire repeatedly into mercury, while each metal is connected with a pole of a battery. It may be kept for a long time in perfectly dry air, but in moist air it oxidises rapidly, forming a growth of pure alumina which makes an attractive lecture experiment.

THE latest issue of the *Izvestia* of the East Siberian branch of the Russian Geographical Society (vol. xxvi., Nos. 4 and 5, Irkutsk, 1896) contains various matters of interest. It begins by an elaborate paper, by A. A. Kaufmann, on the complex forms of land tenure in Siberia. An immense mass of data relative to this question has lately been accumulated by the surveys and explorations which have been made in Siberia, in order to ascertain the area of land which remains free for the new-coming settlers, and the results of these elaborate researches and surveys were embodied in a series of volumes, published by the Ministry of State domains, under the name of "Materials relative to the economical conditions of the peasants in Siberia." M. Kaufmann now sums up the results of these researches, which are the more important as they show what forms of land tenure have been developed by the immigrants themselves, who had been left absolutely free to occupy immense tracts of waste land, and to work out such forms of land tenure as they themselves found convenient. A very great variety of forms of land tenure has thus come into existence in both West and East Siberia, nearly all hitherto known forms of land tenure being represented on this vast area, with the exception of only one, namely the private, hereditary and individual ownership of the land. This last does not exist, while communal possession is everywhere the rule, and it takes a quite unsuspected variety of forms. The prevailing form is the possession by a group of villages, or by the canton or Volost, which includes from ten to fifteen separate villages, and usually has several thousands of inhabitants, who consider the land of the Volost as their common possession, and allot and re-allot it according to their respective needs. Within the estate of the Volost, again, a great variety of forms of land tenure is found, and very often strangers to the canton are also admitted to the temporary possession of parts of the Volost's estate in exchange for similar rights being granted to the inhabitants of the Volost on the land owned by those strangers. On the whole, M. Kaufmann's essay can be earnestly recommended to the attention of the students of the subject in this country.—Two papers, on the Buryates of Irkutsk, by P. E. Kulakoff, and on the Buryates of Transbaikalia, by M. A. Kroll, are full of interest, as the former contains valuable remarks on the influence of the Shamanist religion, the epidemical insanity which lately prevailed in the Buryate settlements, the influence of contact with the Russians, &c.; while the second has new data upon the tribal organisation, and mentions the interesting fact that the Transbaikalia Buryates do not die out as other natives do, but have doubled their numbers since the beginning of this century.—Three papers, on the Yakutes, deal with the old tribal organisation of the Yakutes, with some graves of the beginning of this century, and with the Yakute tales collected by the late M. Khudyakoff, and lately published at Irkutsk under the name of "Verkhoyanskiy Sbornik."—V. B. Shostakovich contributes a paper on the protective adaptations of the buds in different Siberian trees and bushes (with one plate); and Prof. Katanoff gives an account of the Turkish inscriptions on the Orkhon and the Yenisei.

SOCIETIES AND ACADEMIES.

LONDON.

Chemical Society, November 5.—Mr. A. G. Vernon Harcourt, President, in the chair.—The following papers were read:—The constitution of the so-called nitrogen iodide, by F. D. Chattaway. The most probable formula assignable to

nitrogen iodide is NH_3I_2; it is decomposed by excess of water, giving iodine and ammonium iodide and hypoiodite. The author has examined its reactions.—The carbohydrates of barley straw, by C. F. Cross, E. J. Bevan, and C. Smith. Evidence is adduced which points to the gradual transformation in barley straw, of a hexose into a pentose derivative; a transition form of the constitution $C_5H_8O_3\langle{}^{O}_{O}\rangle CH_2$ appears to exist.—The direct union of carbon and hydrogen, by W. A. Bone and D. S. Jerdan. Much acetylene and some methane are found in dry hydrogen gas in which an electric arc has burnt between carbon poles.—The explosion of acetylene with less than its own volume of oxygen, by W. A. Bone and J. C. Cain.—The refraction constants of crystalline salts, by W. J. Pope. The molecular refractions of crystalline salts, calculated from the several principal refractive indices, is an additive property.—Compounds of metallic hydroxides with iodine, by T. Rettie.—Economical preparation of hydroxylamine sulphate, by E. Divers and T. Haga. Sodium nitrite, sulphonated with sodium sulphite and hydrolysed, yields nearly its own weight of hydroxylamine sulphate.—The reduction of nitrososulphates, by E. Divers and T. Haga. Potassium nitrososulphate, when reduced with sodium amalgam, yields hyponitrite, sulphite, sulphate, amidosulphonate, nitrous oxide, hydrazine, ammonia and nitrogen.—Imidosulphonates, Part ii., by E. Divers and T. Haga.—Amidosulphonic acid, by E. Divers and T. Haga. An economical method of preparing this acid is given, and its properties and reactions are described.—Molecular conductivity of amidosulphonic acid, by J. Sakurai.—The physiological action of amidosulphonic acid, by O. Loew. The salts of this acid seem poisonous only to phænogamous plants, and not to other forms of vegetable or to animal life.—How mercurous and mercuric salts change into each other, by S. Hada.—The effect of heat on aqueous solutions of chrome alum, by Miss M. D. Dougal. Experiments on the diffusion of violet and green chrome alum solutions harmonise with the view that the green solutions contain sulphuric acid and a colloidal chromylsulphuric acid.—On the hydrolysis of ethylic dicarboxylglutaconate, by H. W. Bolam.—The periodic law, by R. M. Deeley.—The colouring matters occurring in various British plants, by A. G. Perkin and J. J. Hummel. The colouring matter of the yellow wallflower (*Cheiranthus cheiri*) consists of quercitin and a new substance, isorhamnetin, $C_{16}H_{12}O_7$; the colouring matter of white hawthorn blossoms (*Cretægus oxyeantha*) is quercitin.—Position-isomerism and optical activity; the comparative rotatory powers of the dibenzoyl- and ditoluyl-tartrates, by P. Frankland and F. M. Wharton.—Researches on the terpenes. VII. Halogen derivates of camphor, by J. E. Marsh and J. H. Gardner. Bromine and phosphorous trichloride convert camphor into two isomeric tribromocamphene hydrobromides, $C_{10}H_{14}Br_4$; they are both convertible into the same tribromocamphene, $C_{10}H_{13}Br_3$. A number of bromo- and chloro-camphene derivatives have been obtained.—Derivatives of camphenesulphonic acids, by A. Lapworth and F. S. Kipping.—Preparation of dimethylketohexamethylene and experiments on the synthesis of dimethylhexamethenylmalonic acid, by F. S. Kipping and W. B. Edwards.—Sulphocamphylic acid, $C_9H_{14}SO_5$, with remarks on the constitution of camphoric acid and of camphoronic acid, by W. H. Perkin, jun. The further study of the decomposition products of α- and β-camphylic acids leads to results which can be explained on the assumption that camphoric acid has the constitution $\begin{matrix}CMe_2\cdot CH_2\cdot CH_2\\ |\qquad\quad |\\ CMe(COOH)CH\cdot COOH\end{matrix}$; this view supports Bredt's formula for camphoronic acid.—On Pettenkofer's method for determining carbonic anhydride in air, by Prof. Letts and R. F. Blake. By employing precautions suggested by the authors, Pettenkofer's method can be made of great accuracy and delicacy.

Geological Society, November 4.—Dr. Henry Hicks, F.R.S., President, in the chair.—The President referred to the loss which the Society had sustained by the decease of Prof. A. H. Green, F.R.S., who had served for some years on the Council, and was Vice-President at the time of his death.—The President announced that Lady Prestwich, in fulfilment of the terms of a bequest of her late husband, had offered to the Society 260 bound volumes of geological tracts from his library. Also that a sum of £800 had been bequeathed to the Society by Sir Joseph Prestwich, the interest to be applied to the triennial award of a medal and fund: this bequest to take effect subsequent to the decease of Lady Prestwich.—Additional note on the sections near the summit of the Furka Pass (Switzerland), by Prof. T. G Bonney, F.R.S. The author, during a visit to Switzerland in 1895, had taken the opportunity of completing the examination of the sections on the western side of the Furka Pass, and of glancing again at those previously studied. His observations support the view that the white, sometimes slightly quartzose or micaceous, marble which crosses the summit of the Pass is a rock much older than the Mesozoic era. Dr. J. W. Gregory thought that Prof. Bonney's maintenance of his former conclusion after a third study of the relations of the saccharoidal and the Jurassic limestones would lessen the value attached to the difficulties of his theory. Neither explanation is free from difficulty, but the constant differences now found between the two rocks greatly increase the probabilities in favour of the fault-theory. In reply the author said they must either assume very peculiar faulting or very sporadic and inexplicable metamorphism—seeing that the marble was totally different from the adjacent Jurassic rocks, was exactly like the marbles elsewhere members of the crystalline schists, and evidently had been affected by pressure after it had become a marble, while the other was simply a limestone affected by pressure. Hence he thought that the hypothesis of faults offered the fewer difficulties.—Geological and petrographical studies of the Sudbury Nickel District (Canada), by Dr. T. L. Walker. Sudbury is a small town situated in Northern Ontario, in the centre of the nickel-mining district. North of the Great Lakes granite and gneiss form almost boundless terranes, interrupted only by belts of Huronian rocks, which are in turn associated with post-Huronian eruptives, the most important of which are the large nickel-bearing massives. The nickel-bearing rocks, which are eruptive, form long elliptical stocks which conform to the strike of the Huronian rocks containing them. Contact-action indicates that they are younger than the rocks previously referred to. The smaller eruptives are composed of greenstone, which appears to have been formed from norite or gabbro. Some of the larger eruptives, however, have been highly differentiated on cooling, as they are now composed of granite and greenstone with gradual transitions from the one to the other. The greenstone generally forms one side of the eruptive, and on the outer border is often characterised by large masses of nickeliferous pyrrhotite, chalcopyrite, and nickeliferous pyrite, with frequent smaller masses of magnetic iron-ore rich in titanic acid. The author regarded these mineral masses as genetically related to the greenstone and granite, in that they appear to be the extreme products of differentiation. About half the world's nickel supply is drawn from these deposits.—On the distribution in space of the accessory shocks of the great Japanese earthquake of 1891, by Dr. Charles Davison. The object of the author in this paper is to consider the geographical distribution of the numerous shocks which preceded and followed the great earthquake of 1891. Reasons were given for believing that the distribution of earthquakes in 1890–91 was little, if at all, due to the marked shock of May 12, 1889, but that the earthquakes of these years were preparatory to the great earthquake, the consequent relief at numerous and widely distributed points equalising the effective strain along the whole fault-system, and so clearing the way for one or more almost instantaneous slips along its entire length. This outlining of the fault-system points to the previous existence of the faults, and implies that the great earthquake was due not to the rupturing of the strata, but probably to the intense friction called into action by the sudden displacement. The distribution of the after-shocks was then discussed, and it was maintained that the after-shocks of the Mino-Owari earthquake for the first fourteen months were subject to the following conditions: decline of frequency, decrease in the area of seismic action, and a gradual but oscillating withdrawal of that action to a more or less central district. Prof. Milne said that the Mino-Owari earthquake had furnished a greater number and a more varied series of seismic phenomena for analysis than had been noted in connection with any disturbance previously recorded. When this earthquake took place an enormous fault, which can be traced over a length of more than forty miles, appeared upon the surface, and it was usually supposed that the sudden rupture and displacement of vast masses of material along this line were the cause of the earthquake. On account of a peculiar distribution of shocks which took place prior to 1891, Dr.

Davison argued that the fault or faults in the Mino-Owari district were outlined before the occurrence of the great earthquake, which was, therefore, only the result of their extension. This may have been so, but it must be remembered that before 1891 the number of shocks occurring in the Mino-Owari plain were not numerous; and as from 1889 to 1891 it cannot be said that they increased in number, while their distribution, as exhibited by maps, was largely dependent upon the observing-stations. Where the maps showed blank spaces, in many cases the country was mountainous, and there were no observers.

Linnean Society, November 5.—Dr. Günther, F.R.S., President, in the chair.—Dr. Morris, C.M.G., Royal Gardens, Kew, exhibited specimens and slides illustrating the occurrence of raphides in the bulbs of the common hyacinth of gardens (*Hyacinthus orientalis* and varieties). Forms of eczema were said to have been produced in persons handling and cleaning these bulbs. Although the fact was familiar to gardeners, the cause did not appear to have been clearly traced. Experiments and observations at the Jodrell Laboratory at Kew had shown that both dry and moist scales were capable of producing considerable irritation in certain cases when applied directly to the skin. There was little doubt that the raphides were the prime agents. These needle-shaped crystals (composed of oxalate of lime) varied from $\frac{1}{100}$th to $\frac{2}{100}$th of an inch in length, and were arranged in close bundles, easily dispersed by rubbing the dry scales. In the growing plants they were doubtless protective, as snails, for instance, avoided hyacinth bulbs, but attacked others growing close by. Roman hyacinths (var. *albulus*) were understood to cause greater irritation than other varieties. Dr. D. H. Scott described some experiments which he had tried, tending to confirm the conclusion that the irritation of the skin produced by contact with the bulb-scales of Hyacinths is due immediately to puncture by the numerous raphides.—On behalf of Dr. H. B. Hewetson, of Leeds, Mr. Harting exhibited photographs of a specimen of Macqueen's Bustard (*Otis Macqueeni*) which had been shot at Easington, in Holderness, on October 17 last, and gave a brief account of the species, which had now been met with in England for the third time; the first instance of its occurrence having been noticed in Lincolnshire in October 1847, and the second in Yorkshire in October 1892.—Mr. Hugh Warrand exhibited a remarkable bird which was believed at first to be a hybrid between the Red Grouse and Ptarmigan, but which in the opinion of Mr. Ogilvie Grant, Mr. Millais, and Mr. Harting, could only be regarded as an abnormally pale-coloured grouse. Only one possible instance had been recorded of such a hybrid as was suggested, viz. in the case of a bird which was exhibited some years ago by Prof. Newton to the Zoological Society (*P. Z. S.*, 1878, p. 793) and had since been figured by Mr. Millais in his work on Game Birds. A specimen of the Cream-coloured Courser (*Cursorius isabellinus*), an extremely rare visitor to this country from North Africa (probably *vid* Spain), which had been shot on Salisbury Plain, at Earlstoke, on October 10 last, was exhibited by Mr. Harting, who gave particulars of the occurrence, and stated that another example of this bird had since been obtained in Bouley Bay, Jersey.—A paper by Mr. A. W. Waters, on Mediterranean Bryozoa was then read. Dealing in the first place with some *Cellulariidæ* and other Bryozoa from Rapallo, the paper was to some extent a revision of work already published on Mediterranean Bryozoa. Stress was laid upon the importance of noting the position from which the radicle-tube grows, and this was found to be a character of specific value.—Dr. S. Schönland communicated a paper on some new species of *Crassula* from South Africa, which he had obtained from localities which had been very rarely visited by botanical collectors, and which were believed to be undescribed. Mr. J. G. Baker, who criticised the paper, spoke in favourable terms of the care which had been taken by the author in its preparation, and thought there was sufficient justification for describing the species mentioned as new.—A revisionary monograph of the New Zealand Holothurians, by Prof. A. Dendy, of Christchurch, N.Z., was read.—The Rev. J. Whitmee made some remarks on the Trepang fishery in Samoa, where several edible species of Holothurians are gathered and prepared for the market, and called attention to the well-known fact that a small fish of the genus *Fierasfer* used the body of the Holothurian as a habitation.

Mathematical Society, November 12.—Major MacMahon, R.A., F.R.S., President, in the chair.—The President briefly stated the grounds of the award by the Council of the De Morgan medal to Mr. S. Roberts, F.R.S.; and after receiving the medal, Mr. Roberts thanked the Council and the members for the honour they had conferred upon him, and said that his connection with the Society had been of great service to him.—The ballot was then taken, with the result that the gentlemen whose names are given in NATURE for October 22, were declared to be duly elected to form the Council for the ensuing session.—Prof. Elliott, F.R.S., having taken the chair, called upon Major MacMahon to read his address, which was on "The Combinatory Analysis." Mr. S. Roberts gave, in abstract, an account of Herr E. Lasker's "Essay on the Geometrical Calculus, Part 1." The titles only of the following papers were read, owing to the lateness of the hour:—"Symbolic Logic," H. MacColl; "On a General Integral with some physical applications," G. J. Hurst; "On Ratio," Prof. M. J. M. Hill, F.R.S.; "On the Geometrical Construction of Models of Cubic Surfaces," W. H. Blythe; "Theory of Vortex Rings," H. S. Carslaw; "Differentiation of Spherical Harmonics," E. G. Gallop; "On the Application of Jacobi's Dynamical Method to the General Problem of Three Bodies," and "On certain properties of the mean motions and the secular accelerations of the principal arguments used in the Lunar Theory," Prof. E. W. Brown; "Note on the Symmetric Group," Prof. W. Burnside, F.R.S.; "Note on the Capacity of a Conductor in the form of two intersecting spheres," W. D. Niven, F.R.S.

CAMBRIDGE.

Philosophical Society, October 26.—Prof. Hughes, Vice-President, in the chair.—The following elections were made:—President: Mr. F. Darwin. Vice-Presidents: Prof. G. D. Liveing, Prof. Newton, Prof. J. J. Thomson. Treasurer: Mr. Glazebrook. Secretaries: Mr. Newall, Mr. Bateson, Mr. Baker. Ordinary Members of Council: Dr. Gaskell, Mr. Marr, Mr. Larmor, Dr. Marshall Ward, Mr. Shipley.—Mr. F. Darwin, President, then took the chair.—Mr. S. F. Harmer exhibited the casts of *Iguanodon bernissartensis*, Boulenger, recently presented to the Museum of Zoology by H.M. the King of the Belgians. The casts are reproductions of some of the famous specimens preserved in the "Musée Royal d'Histoire Naturelle de Belgique," at Brussels. These specimens were discovered in April 1878, in the colliery of Bernissart, a village situated between Mons and Tournai, close to the French frontier. The bones, which are of Wealden age, were found at a depth of 356 metres (322 metres below sea-level). Nearly thirty complete skeletons, belonging to full-grown individuals, were found at the time of the original discovery, or at a later period; the great majority belonging to *I. bernissartensis*, and the others to *I. mantelli*, well known in England through the labours of Mantell, Owen and others. Although much had been done in England and elsewhere, towards understanding the structure of *Iguanodon*, no skeleton which was more than fragmentary had been described before the Belgian discoveries were made. Prof. Newton stated that the importance attached by many high authorities to the group of Dinosaurs known as *Ornithopoda*, from their resemblance in several points to the class *Aves*, had long made him desirous of obtaining for the Museum of Zoology a cast of one of the famous Belgian *Iguanodon* skeletons. About a year ago he mentioned the subject to the High Steward of the University, who, with his accustomed kindness and energy, at once asked Her Majesty's Minister at Brussels to find out on what terms the want could be supplied. In due time an answer was received by Lord Walsingham that this could be done by the University paying for the cast or offering in exchange specimens to the value of 200*l*. Meanwhile the subject had been also mentioned to the late Lord Lilford, who had for many years been so great a benefactor to the museum, and he at once addressed the late Rev. Horace Waller, well known as a companion of Livingstone. Mr. Waller suggested an application to King Leopold himself, through his personal friend Sir John Kirk. To this Sir John readily consented, and, on His Majesty visiting London last winter, made known to him how acceptable the gift of a cast would be. The King was graciously pleased to entertain the application favourably, and gave orders accordingly, with the result that after a short correspondence with M. Dupont, the Director of the Museum at Brussels, not a single cast only, but the magnificent series now exhibited arrived in the course of the summer, and owing to the royal donation having liberally included the necessary ironwork, the skeleton was mounted without difficulty. Though the thanks of the Senate have been most properly offered to H.M. the King of the Belgians for his

great munificence, and this token of his good will, the gratitude of all here is equally due to Sir John Kirk, without whose kind and ready intervention, the University would have been unable to procure this desirable acquisition.—Remarks on the structure and affinities of *Iguanodon*, by Mr. H. Gadow. Though birds are descendants of some reptilian stock, it was held that the particular group of ancestral reptiles is not to be found among the Iguanodonta, not even among the much wider group of Dinosauri, in spite of the close resemblance of the pelvis and most parts of the hind-limbs with the corresponding organs in birds. The composition of the skull, the formation of the fore-limbs, and the palæontological evidence absolutely forbid such an intimate connection with birds. Bipedalism, upright gait, is a feature which has been acquired independently and at various geological epochs by the most heterogeneous creatures, for instance by kangaroos, jerboas, birds, iguanodonts, and even by chlamydosaurus, the peculiar frilled lizard of Queensland.—Notes on cyclostomatous polyzoa, by Mr. S. F. Harmer.

DUBLIN.

Royal Irish Academy, November 9.—The Earl of Rosse, President, in the chair.—Dr. R. F. Scharff read a paper on the origin of the European fauna. In a previous paper he had dwelt on the importance of, in the first place, ascertaining the facts relating to the origin of the fauna of a small area, such as that of Great Britain or Ireland. If that of Great Britain be closely examined, its fauna will be found to consist of three elements, viz. northern, southern, and eastern. There is also a mass of evidence to prove that this latter element reached England after the others, and this is strengthened by the fact that the eastern fauna, which in many respects corresponds with the so-called Teutonic flora, is absent from Ireland. If the geological date of the arrival of this eastern, or, as it might be called, Siberian fauna into England, could be even approximately ascertained, the period of the migration of the southern and northern faunas could also be fixed as taking place at an earlier period, while the separation of Ireland would have occurred at a time intermediate between these events. Dr. Scharff showed that not only was the lower continental boulder clay an undoubtedly marine deposit, but that the eastern or Siberian migration-forms all occur in inter-glacial or later deposits, overlying the boulder clay. The very earliest members of that migration arrived in England during the deposition of the forest bed; so that the newest English, so-called, pliocene crags would therefore be contemporaneous with the lower continental boulder clay. The faunistic evidence proved that the land connection between Ireland, Scotland and Scandinavia, existed until a much later period, and that the Arctic marine fauna which is found in the newer English crags came direct from the Arctic Ocean across the plains of Northern Europe. At that period it was suggested that the Arctic Ocean was completely separated from the Atlantic Ocean. To enable the mammoth to cross from Asia, with other large mammals, the American and Asiatic continents must have been connected at Behring's Straits, whilst another mass of land stretched from Arctic America by way of Greenland and Spitzbergen to northern Scandinavia. The Arctic Ocean swept over Russia and Northern Germany, as far as the east coast of Great Britain. The climatic conditions of European land as then existing were peculiar; while the west coasts of the British Islands and Scandinavia were bathed by the waters of the Gulf Stream, the eastern shores of these countries were lashed by the waters of the Arctic Ocean. There therefore existed the necessary conditions for an excessive snowfall and consequent glaciation on the territories between the two oceans, without requiring any very extreme lowering of the temperature in Northern Europe—viz. evaporation of the warm waters from the Gulf Stream, and the condensation of these vapours on their coming into contact with the cold air from the Arctic Sea.—A paper on the melting point of some minerals, being work done in the Physical Laboratory of Trinity College, Dublin, by Mr. Ralph Cusack, was communicated by Prof. G. F. Fitz-Gerald, F.R.S.—Sir Robert Ball, F.R.S., communicated a memoir, being the eleventh, on the theory of screws, entitled "Further development of the relations between impulsive screws and instantaneous screws."—Several recently-published parts of the thirtieth volume of *Transactions* were laid on the table.

PARIS.

Academy of Sciences, November 16.—M. A. Cornu in the chair.—The Perpetual Secretary announced to the Academy the loss it had sustained by the death of M. H. Gyldén, of Stockholm, Correspondent in the Astronomical Section.—Notice on the work of M. Hugo Gyldén, by M. O. Callandreau.—Researches on phosphoric acid; estimation of pyrophosphoric acid, by MM. Berthelot and G. André. The pyrophosphoric acid is precipitated as magnesium pyrophosphate in presence of an excess of acetic acid, by a mixture of magnesium chloride, ammonium chloride, and ammonium acetate. Test analyses are given showing the accuracy obtainable by this method.—Transformations of pyrophosphoric acid, by MM. Berthelot and André. The acid was prepared by the action of an aqueous solution of hydrogen sulphide upon the lead salt. The aqueous acid is very slowly converted into orthophosphoric acid, 87 per cent. remaining unchanged after five days' standing, 43 per cent. after 121 days, no metaphosphoric acid being formed. The velocity of transformation is greater the more concentrated the solution.—On the earths of the yttrium group contained in the monazite sands, by MM. P. Schutzenberger and Boudouard. Two methods have been tried for the separation of these earths, the fractional crystallisation of the sulphates from the hot aqueous solutions, and the partial decomposition of the nitrates. All attempts at separation by the first method proved ineffectual, but the fractional decomposition of the nitrates by heat gave better results, fractions being obtained with atomic weights varying between 92 and 148. Only one spectrum, however, that of yttria, was given by all the fractions.—Determination of the positions of Santa Cruz, Teneriffe, Saint Louis (Senegal), and Dakar: measurement of the acceleration due to gravity, by M. Bouquet de la Grye.—Memoirs on some problems in navigation and on magnetic observations at sea, by M. Guyou.—On an extension which may be given to a theorem by Poisson, relating to the invariability of the axes, by M. H. Andoyer.—On the convergence of uniform substitutions, by M. E. M. Léméray.—On surfaces of lines of isometric curvature, by M. T. Craig.—Some problems in rigid mechanics, by M. René de Saussure.—On the permanent changes of glass, and the displacement of the zero points of thermometers, by M. L. Marchis. With a view of studying the laws regulating the changes of zero in mercury-glass thermometers, a glass was purposely chosen that should make these changes as large as possible. The experiments were conducted at temperatures between $-60°$ C. and $357°$ C.—Influence of magnetisation upon the electromotive force of a thermo-couple, of which iron is one of the elements, by MM. U. Lala and A. Fournier. A diminution of the electromotive force was observed to take place when the couple was placed in a strong magnetic field.—The absolute measurement of small thicknesses, by MM. Ch. Fabry and A. Perot.—On the densities of nitrogen, oxygen, and argon, and the composition of atmospheric air, by M. A. Leduc (see p. 84).—On a law relating to water vapour, by M. Rateau.—On a new tap for use with compressed gas-cylinders. This tap is so constructed as to allow rapid filling during compression, but to prevent the rapid exit of the gas. It is especially suitable for use with liquefied acetylene.—The neutrality of salts with reference to coloured indicators, by M. H. Lescœur. The blueing of litmus, or reddening of phenol-phthalein, is regarded as indicating not the change from acidity to alkalinity, but from neutrality to alkalinity. With methyl orange, on the contrary, the change to yellow indicates the change from acidity to neutrality. A salt would, from this point of view, be defined as neutral if methyl orange and phenol-phthalein remained colourless, and litmus remained red. Under this definition, such salts as alum and zinc sulphate would be neutral.—Action of sulphuric acid and iodine upon iodic acid. Practically pure iodic anhydride in crystals can be obtained by recrystallising the crude substance from concentrated sulphuric acid to which a little fuming nitric acid has been added.—Analysis of air by *Agaricus atramentarius*, by M. T. L. Phipson. The absorption of oxygen from a confined volume of air by this fungus appears to be as complete as with phosphorus.—On some properties of pure glucina, by M. P. Lebeau. Glucina melted in the electric furnace has its density practically unchanged. The oxide is not reduced by heating with magnesium, sodium, potassium, or aluminium, but boron, silicon, and carbon can reduce it with the formation of crystalline compounds.—On an iodide of molybdenum, by M. Guichard. By the action of hydrogen iodide upon the chloride $MoCl_2$, the iodide MoI_2 can be prepared in the amorphous state.—On the separation of tungsten and titanium, by M. Ed. Defacqz.—The spectrum of chlorophyll, by M. A. Étard. The conclusion is drawn that several distinct green colouring matters have been described under the name of chlorophyll.—On the fixation of

atmospheric nitrogen by the association of algæ and bacteria, by M. Raoul Bouilhac.—The organic material of the mineral water from Tulle-Haut, by M. F. Garrigou. The residue from thirty litres of this mineral water gave reactions indicating the presence of an alkaloidal substance.—On the distribution of lipase in the organism, by M. Hanriot. Various parts of the body were examined, but lipase was only found in notable quantity in the serum, pancreas, and liver.—The achromatometer, by M. A. M. Bloch. An instrument to measure the pressure necessary to decolourise and render bloodless a limited portion of tissue. It differs from previous instruments of the same class in that its use is not limited to the horizontal position.—On the parasitism of the *Monstrillidæ*, by M. A. Giard. The *Monstrillidæ* offer the first example of a parasitic crustacean.—Researches on the morphology of *Trichomonas intestinalis*, by M. J. Kunstler.—Ravages caused in Algeria by the caterpillars of *Sesamia nonagrioides* (Lefevre) to maize, sugar-cane, and other plants, by M. J. Kunckel d'Herculais. Observations on the habits, and on the best means of combating this pest.—On the pool of Berre, and pools situated in its neighbourhood, on the coast of Provence, by M. André Delebecque.—On the subterranean streams near Vercors (Drôme), by MM. E. A. Martel and A. Delebecque.—Relations between lunar movements and barometric movements on the northern hemisphere, by M. A. Poincaré.—Extraordinary rains: the pink rain at Croisic (Loire-Inférieure) of November 8, 1896.

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 26.

ROYAL SOCIETY, at 4.30.—Mathematical Contributions to the Theory of Evolution. On Telegony in Man, &c.: Prof. Karl Pearson, F.R.S., and Miss Alice Lee.—On the Magnetic Permeability of Liquid Oxygen and Liquid Air: Prof. Fleming, F.R.S., and Prof. Dewar, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—The Telephone Trunk Line System in Great Britain: J. Gavey. (Continuation of Discussion.)

SOUTH LONDON ENTOMOLOGICAL AND NATURAL HISTORY SOCIETY, at 8.—Exhibition of Varieties in all Orders.

FRIDAY, NOVEMBER 27.

PHYSICAL SOCIETY, at 5.—Apparatus for giving Diagrams of the Efficiency of a Photographic Shutter: Captain Abney, F.R.S.

MONDAY, NOVEMBER 30.

SOCIETY OF ARTS, at 8.—The Use of Gas for Domestic Lighting: Prof. Vivian B. Lewes. (Three Lectures.)

INSTITUTE OF ACTUARIES, at 7.—Inaugural Address by the President, T. E. Young.

TUESDAY, DECEMBER 1.

ZOOLOGICAL SOCIETY, at 8.30.—On the General Results of his Zoological Expedition to Madagascar: Dr. Forsyth Major.—Notes on a Collection of Reptiles and Batrachians made in the Malay Peninsula, with a List of the Species hitherto recorded from that Region: Stanley S. Flower.—Description of New Fishes from the Upper Shiré River, British Central Africa, collected by Dr. Percy Rendall, and presented to the British Museum by Sir Harry H. Johnston, K.C.B.: G. A. Boulenger, F.R.S.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Paper to be further discussed: The Bacterial Purification of Water: Percy F. Frankland, F.R.S.

WEDNESDAY, DECEMBER 2.

SOCIETY OF ARTS, at 8.—The Teaching of Economics: W. A. S. Hewins.

GEOLOGICAL SOCIETY, at 8.—Another Possible Cause of the Glacial Epoch: Prof. Edward Hull, F.R.S.—On the Affinities of the Echinothuridæ and on Pedinothuria and Elikodiadema, Two New Genera of Echinoidea; On Echinocystis and Palæodiscus, Two Silurian Genera of Echinoidea: Dr. J. W. Gregory.

ENTOMOLOGICAL SOCIETY, at 8.

SOCIETY OF PUBLIC ANALYSTS, at 8.—Some Analyses of Water from an Oyster Fishery; Note on Weighing out Fats; Remarks on Formaldehyde: Chas. E. Cassal.—Note on Formalin: Dr. Samuel Rideal and Ronald Orchard.—Notes on Prussian Blue: Frank H. Leeds.—The Estimation of Borax and Boracic Acid in Milk: Frank P. Perkins.—Note on Copper in Oysters: W. F. Lowe.—The Statement of Analytical Results: J. F. Liverseege.

THURSDAY, DECEMBER 3.

LINNEAN SOCIETY, at 8.—Does Natural Selection play any part in the Origin of Species among Plants: Rev. Geo. Henslow.

CHEMICAL SOCIETY, at 8.—Election of Fellows.—Constitution and Colour: Arthur G. Green.—Some Experiments on Sea-water: E. Sonstadt.—Derivatives of α-Hydrindone: C. Revis and Dr. F. S. Kipping.—Notes on Nitration: Dr. H. E. Armstrong.—2:3′ Bromobetanaphthol: Dr. H. E. Armstrong and W. A. Davis.—Derivatives of Nitrobetanaphthols: W. A. Davis.—Morphotropic Relations of Betanaphthol Derivatives: W. A. Davis.—Researches on Tertiary Benzenoid Amines: Miss C. Evans.

FRIDAY, DECEMBER 4.

GEOLOGISTS' ASSOCIATION, at 8.—The Foraminifera of the Thanet Beds of Pegwell Bay: H. W. Burrows and Richard Holland.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Address by J. Wolfe Barry, C.B., F.R.S. (President).—Railway Signalling: David W. Kinmont.

SUNDAY, DECEMBER 6.

SUNDAY LECTURE SOCIETY (St. George's Hall), at 4.—New Zealand—the World's Wonderland: W. Herbert-Jones.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Habit and Instinct: C. Lloyd Morgan (Arnold).—Gleanings from the Natural History of the Ancients; Rev. M. G. Watkins (Stock).—The Metric System of Weights and Measures: Prof. W. H. Waggstaff (Whittaker).—The Dynamo: C. C. Hawkins and F. Wallis, 2nd edition (Whittaker).—Auto-Cars: D. Farman (Whittaker).—"Carriages without Horses shall go": A. R. Sennett (Whittaker).—Transformers for Single and Multiphase Currents: G. Kapp (Whittaker).—A-birding on a Bronco: F. A. Merriam (Boston, Mass., Houghton).—Prehistoric Man and Beast: Rev. H. N. Hutchinson (Smith, Elder).—Cambridge Natural History. Vol. 2. Worms, Rotifers, and Polyzoa: Gamble, Sheldon Shipley, Hartog, Benham, Beddard, and Harmer (Macmillan).—Hindu Astronomy: W. Brennand (Straker).—The Earth and its Story: Prof. A. Heilprin (Gay and Bird).—British Patent Laws and Patentees' Wrongs and Rights: H. Haes (Whittingham).—Elements of Differential Calculus: Prof. E. W. Bass Chapman).—Locomotive Mechanism and Engineering: H. C. Reagan, jun., 2nd edition (Chapman).—Notes for Chemical Students: Prof. R. T. Austen, 2nd edition (Chapman).—Experiments upon the Contraction of the Liquid Vein issuing from an Orifice: H. Bazin, translated by J. C. Trautwine, jun. (Chapman).—A Text-Book on Shades and Shadows and Perspective: J. E. Hill, 2nd edition (Chapman).—Tables for Iron Analysis: J. A. Allen (Chapman).—Handbook of Courses open to Women in British, Continental, and Canadian Universities: J. Maddison (Macmillan).—Journal and Proceedings from the Royal Society of New South Wales for 1895, Vol. xxix. (Sydney).—Report of the Commissioner of Education for the Year 1893-4, Vol. ii. (Washington).—Botanical Microtechnique: Dr. A. Zimmermann, translated by J. E. Humphrey (Constable).—The True Grasses: E. Hackel, translated by F. Lamson-Scribner and E. A. Southworth (Constable).—Charles Pritchard, D.D., F.R.S., &c.: A. Pritchard, and others (Seeley).—Chemistry for Engineers and Manufacturers. Vol. 2. Chemistry of Manufacturing Processes: B. Blount and A. G. Bloxam (Griffin).—Select Methods in Inorganic Quantitative Analysis: Prof. F. C. Smith (Edinburgh, Clay).—Among British Birds in their Nesting Haunts, illustrated by the Camera: O. A. Lee, Part 1 (Edinburgh, Douglas).

PAMPHLETS.—Sulla Propagazione dell' Elecrtricita nei Gas Attravusati dai Raggi di Röntgen: Prof. A. Righi (Bologna).—The Principal Household Insects of the United States (Washington).—Revue Météorologique. Travaux du Réseau Météorologique du Sud-Ouest de la Russie dix ans d'Existence: A. Klossovsky (Odessa).

SERIALS.—Encyklopædie der Naturwissenschaften, Erste Abthg, 69 to 70 Liefg., Dritte Abthg, 34 to 37 Liefg. (Breslau, Trewendt).—The Bachelor of Arts, November (New York).—Physical Review, Vol. iv. No. 2 (Macmillan).—Publications of the Leander McCormick Observatory of the University of Virginia, Vol. 1, Part 7 (Charlottesville).—Proceedings of the American Academy of Arts and Sciences, new series, Vol. xxiii. (Boston, Mass., Wilson).—Morphologisches Jahrbuch, 24 Band, 3 Heft (Leipzig, Engelmann).—Centralblatt für Anthropologie, &c., 1896, Heft 4 (Breslau, Kern).—Astrophysical Journal, November (Wesley).

THE YAKOUTI.

Description of the Ethnographical Researches of V. A. Sierochevsky. Published by the Imperial Geographical Society of Russia, and edited by Prof. N. E. Vesilofsky. Vol. i. pp. 720, with 168 sketches, portraits, and a map. (Dedicated to the memory of A. F. Middendorf).

THE district occupied by the tribes with which this volume deals, is of vast extent, embracing almost the whole north-eastern corner of Siberia, and having a superficial area of over 2,000,000 square miles, with a seaboard to the Arctic Ocean of about 3000 versts, extending from west to east, the depth from north to south being half that amount.

If a semicircle with a radius of about 1300 miles be drawn from a point where the most western arm of the Lena enters the Arctic Ocean, this region virtually embraces the whole country inhabited by the Yakouti. The periphery of this semicircle consists of mountains varying in height from 1200 to 4000 feet, which throw off very numerous outliers into the interior table-land, giving to the scenery a romantic and picturesque character.

The interior is watered by a large number of rivers, many of them of considerable volume with swift currents; of these the northern flow into the Arctic Ocean, and the southern into the Lena, which has over a thousand tributaries. This river and the Aldana are the two most important; the latter having a length of over 2000 versts. The author had special opportunities of studying this interesting region, for not only after the date of his arrival, in 1880, did he traverse it in various directions, but from 1887-1892 he occupied himself with farming, making at the same time a close study of the language, manners, and customs of the inhabitants.

As a result, we have presented to us a volume dealing comprehensively with the history, geography, physical conditions, and ethnography of the country, and giving evidence of that painstaking and minute research so often characteristic of both Russian and German writers.

How sparsely this immense region is inhabited may be inferred from the fact that the native population does not exceed 200,000, about equally divided between the two sexes, and it mostly congregates along the banks of the rivers on the southern plateau between the Lena and the Aldana, the vast interior being virtually a *terra incognita*.

The author is inclined to the opinion that the Yakouti are not of Mongolian, but of Turko-Tartar origin, and in support of this view, which is that of the people themselves, recites numerous legends and traditions, considering it a not unimportant corroboration, that within six months from their arrival Tartars are able to understand the language, which for Russians requires years of residence to learn.

The Yakouti are in a high degree a mixed race, owing to intermarriage with the Tungoose and Russian; are short of stature, their average height being 5 ft. 3 in. as against 5 ft. 7 in. for the Russian; are generally dark, having brilliant black eyes set deep in narrow orbits; thus, although they have something in common with the Mongol, yet the author considers them to bear a much closer resemblance to the Red Indian of America.

Their religion is nominally that of the orthodox Greek church; but they are intensely superstitious, having a profound faith in good and evil spirits, and considering their sick to be possessed; they also practise exorcism, and believe in the efficacy of amulets and charms.

Their system of government is primitive and patriarchal, the elders exercising unlimited control over all tribal or family disputes. Owing to their clannishness it is almost impossible for a stranger to obtain redress, and the writer affirms that were the jury system to be introduced, no Yakouti jury would ever condemn a fellow countryman. Blood feud is, however, recognised to the ninth generation, but the feud can be ended for a consideration in money or goods.

Their language is, according to Bolling and Vambëry, an independent branch of the Turko-Tartar group, having at most ten to twelve thousand words. Inflections, however, are very numerous, and these are only to be learned from a residence amongst them; but, the author adds, to perfectly understand it, one must be a Yakout.

As may readily be believed, the climate in these high latitudes is extremely cold, and the number of days that at Yakutsk are free from frost during the year, do not exceed ninety-nine, yet during this brief period cereals grow and ripen, giving favourable returns; Kuban, a hard wheat, ripening in eighty days; other wheats in seventy-seven days; rye, barley, and oats in seventy-one days. Of these they cultivate sufficient for their requirements and to interchange for manufactured products.

Commencing towards the middle of September, frost continues to the middle of May, and before October 15 the whole region is covered with a solid mantle of snow and ice, which never melts until, under the influence of south-west and westerly winds, the thaw sets in at the end of April. The temperature throughout the winter varies but little, being from -48° Celsius to -67°; and it is remarkable that the cold is more intense in the southern than in the northern zone. The climate is exceedingly dry and exhilarating; day and night temperatures are identical, and there is not sufficient wind to winnow corn or move a branch. Throughout these months nature is in her deepest sleep. The sole evidence of faunal life is that of an occasional fox or hare; but no birds wing their flight, and desolation reigns supreme. Indeed, nowhere else in the world does winter reign under such calm, undisturbed conditions.

With the approach of spring the weather becomes disturbed, and under the influence of the south-south-west and westerly winds, as if under the power of a magician's wand, summer bursts upon the land. In the figurative language of the natives, "Winter is a white ox with two horns, one of which is broken on the first Athanasius (March 5), the second on the second Athanasius (April 24), and on the third Athanasius (May 14) the whole body disappears."

The summers are very hot, so that the variations are extreme. At Yakutsk the mean winter temperature is $-54{\cdot}5$, the summer $+22{\cdot}4$; at Verchoiansk, -58 and $+28{\cdot}2$.

The country is well wooded, forests of pine, fir, and birch extending for hundreds of miles along the rivers and the tundras of the north. They occupy about 70 per cent. of the land surface, but towards the north the trees become stunted and deformed, few of them attaining a height of over 30 feet, or a diameter of 6–8 inches. So useless is the timber, that the few natives resident there are forced to import wood for their structural requirements from the south.

The author enters minutely into the social life of the people, and into their marriage customs and home life. Had the work been printed in any other language than the Russian, it would doubtless have found readers over a wide circle. W. F. H.

CHEMICAL DYNAMICS.

Studies in Chemical Dynamics. By J. H. van 't Hoff. Revised and enlarged by Dr. Ernst Cohen. Translated by Dr. Thomas Ewan. Pp. vi + 286. (Amsterdam: F. Müller and Co. London: Williams and Norgate, 1896.)

IN 1884 Prof. van 't Hoff published a small volume entitled "Études de dynamique chimique," the general purpose of which was to give an account of the course of chemical change as illustrated by experiments chiefly carried out in his own laboratory. Unfortunately for the little work, it appeared at a time immediately following the general recognition of the immense service done by its author to organic chemistry in putting forward the idea of the asymmetric carbon atom, and immediately preceding the period when he equalled his former success by propounding the theory of osmotic pressure. There can be little doubt that the extraordinary fertility of these hypotheses, and the rapid experimental progress made in their development, diverted from the "Études" the attention they deserve. The book suffered neglect even on the continent, and in this country has been little more than a name. Such neglect is all the more regrettable because the "Études" give an excellent insight into the author's manner of work. The brilliant theories with which his name is associated were no sudden inspirations, but the outcome of steady and systematic research and speculation. It is interesting to note, for example, that in the "Études" the author makes use of Pfeffer's experiments with semi-permeable membranes, in order to calculate the affinity of salts for their water of crystallisation, and has clearly before him the connection between the lowering of the vapour pressure and the pressure developed in Pfeffer's cells.

The book at present under notice is the translation of a German edition of the "Études," revised and enlarged by Dr. E. Cohen. The form of the original work has been retained, but many later experiments have been added. Notwithstanding the interest of these additions, one almost regrets that the translation is not that of the unmodified work, on account of its value as an historical document. The book is divided into four parts, entitled: (1) "The Course of Chemical Change"; (2) "The Influence of Temperature on Chemical Change"; (3) "Chemical Equilibrium"; (4) "Affinity." In each part we have a theoretical discussion of the subject, accompanied by numerous examples and applications. The experimental devices described are often extremely ingenious, and no worker in physical chemistry should neglect to make himself acquainted with them. As to the thread of reasoning which binds the various pieces of research together, it must be conceded that the student may occasionally find some difficulty in following it. The book is not altogether easy reading, and its form precludes it from ever becoming a popular text-book. But it is much more than a text-book: from it every earnest student of physical chemistry will receive both insight and inspiration.

Among the chief novelties of the new edition may be mentioned the experiments made by the author and his pupils on slow oxidation, the thermodynamical proof of the important relation $d \log K/dT = q/2T^2$, and the methods for the determination of transition temperatures. It should be added that Dr. Ewan's translation is in refreshing contrast to many of the versions of foreign works on chemistry that have recently come under our notice. J. W.

ORIENTAL WIT AND WISDOM.

The Laughable Stories collected by Mâr Gregory John Bar-Hebræus, Maphrian of the East, from A.D. 1264 *to* 1286. The Syriac text, edited with an English translation. By E. A. Wallis Budge, Litt.D. (Cantab.), F.S.A. Pp. xxvii + iv + 204 + 166. (Luzac's Semitic Text and Translation Series. Vol. i., 1897.)

THE laughable stories collected in the thirteenth century by Bar-Hebræus, the Syriac text of which, together with an English translation, has just been published by Dr. Wallis Budge, is a remarkable book in many ways. It has been the custom with many writers who have concerned themselves with the legends and history of the East, to laugh at the Syrians as a purely ecclesiastical people whose writings consisted solely of religious commentaries and pious disquisitions; Syriac literature, in fact, has been left to the theologian, and the student of folk-lore has looked elsewhere for his materials. That this was to some extent a prejudiced view to take, was evident after the publication in 1885 of "Ka-lîlah and Dimnah," by the late Mr. Keith-Falconer, and from the Syriac version of the "History of Alexander the Great," published four years later by Dr. Wallis Budge; both of these books abundantly proved, if proof were needed, that Syriac writers took an intelligent interest in the literatures of other nations, and that from the translations they made for the use of their own countrymen, much valuable evidence was to be obtained with regard to the growth and development of Eastern legends and myths. From such works as these, however, to the book before us is a far cry, for no one has hitherto suspected that in the most learned Maphrian of the East, the Jacobite Church possessed a veritable Joe Miller.

In the course of a long life devoted to the study of theology, philosophy, and history, Bar-Hebræus, besides acquiring a thorough knowledge of the writings of his own countrymen and those of the Jews, also became

acquainted with much of the literature of Arabia, Persia, India, and Greece. While so engaged, whenever he came across a story or an anecdote that struck his fancy he made a note of it, and towards the end of his life the notes he had thus collected he classified, and from them he composed the book of laughable stories which is now rendered accessible to Western readers. A few of these stories have been previously published by Adler and Morales from a MS. in the Vatican, but the whole number, 727 in all, have now been published by Dr. Budge. The MS. in the author's own possession, which he has used as the base of his text, was written by a scribe who omitted some of the stories that he considered were not edifying; but these gaps Dr. Budge has fortunately been able to supply from a MS. in the India Office, so that there is every reason to believe that we now have the work in the exact form in which it left the hands of Bar-Hebræus. In the India Office MS., though the scribe did not go so far as to omit any of the stories, a note is frequently put in the margin as to what the reader is to skip and what to read; but, as Dr. Budge points out, the Western reader will probably doubt the wisdom of the man who made the selection. Dr. Budge himself has given us the book as Bar-Hebræus wrote it, though in his translation several of the stories, for obvious reasons, have been turned into Latin.

From a scientific point of view this collection of stories is of the highest importance, for not only do they illustrate the differences exhibited by Eastern and Western ideas of wit and humour, but we also find among them many interesting variations and developments of older traditions and beliefs. "Some of the stories," Dr. Budge remarks in his introduction, "may have existed in more than one form, or they may have been told in different ways. Thus in No. ccclxxx., the scarabæus is made to say to its mother, "Whithersoever I go men spit upon me," and its mother replies, "It is because thy beauty and smell are pleasant." With this may be compared the Arabic proverb, "The beetle is a beauty in the eyes of its mother." Again, in No. ccclxxv. we have the story of the ape of the mosque and the dog, but the turn given to the story is quite different from that of the Arabic version. We may also notice, in passing, that stories told of one man by one author are told of some one quite different by Bar-Hebræus. Thus in No. iv. it is said that Socrates once saw a woman who had hanged herself, and that he remarked, "Would that all trees bore such fruit as this; but in Diogenes Laertius the saying is attributed to Diogenes the Cynic. . . ." Dr. Budge has in this manner been able to indicate the sources from which several of the stories are derived, and to trace their subsequent development; the great majority, however, are entirely new, and are not to be found in any other work at present published.

It would be impossible within the limits of a review to do justice to the book even by lengthy quotations, but some idea of its scope and of the ground it covers may, perhaps, be obtained from a brief *résumé* of the contents of the twenty chapters or headings under which Bar-Hebræus classified his stories. The first eight of these contain notable sayings by sages, philosophers, and various classes of men of different nations; then follow stories of physicians and legends attributed to them, stories of the speech of animals, of men whose dreams and divinations have come true, stories of rich and generous men, of avaricious men and misers, of workmen who followed despised handicrafts, laughable stories of actors and comedians, stories of clowns and simpletons, of lunatics and of men possessed of devils, stories of robbers and thieves, of wonderful accidents and occurrences, and finally a collection of physiognomical characteristics supposed to indicate a man's character or future actions. The chapter or section of most interest to the present writer is that dealing with dreams and divination, for in these stories we see the survivals of a complicated system of divination and sorcery that flourished in Western Asia more than 2000 years before the birth of Bar-Hebræus; in so varied a collection, however, it is probable that each reader will find something of interest for himself. In conclusion, we may add that Dr. Budge is to be congratulated on having opened up this rich field of study for all those who may be interested in ancient Oriental customs, legends, or beliefs.

OUR BOOK SHELF.

Biedermann's Electro-physiology. Translated by Frances A. Welby. Vol. i. Pp. xii + 522. (London: Macmillan and Co., Ltd., 1896.)

STUDENTS of physiology who find, as many do, their ignorance of German to be an embarrassing obstacle in their reading, ought to be grateful to Miss Welby for her skilful translation of Prof. Biedermann's "Electrophysiologie," an account of which we gave some time ago to our readers. The value of the book consists chiefly in this—that it is a faithful record of the results yielded by the researches of the last half-century in the field of inquiry to which it relates. Some parts of this field are very unfamiliar to ordinary readers; consequently the difficulty of the translator's task has been considerably increased by the circumstance that many of the words used have as yet no recognised English equivalents. In such a case a choice has to be made between the method of introducing into an English book forms of expression obviously German, and that of devising new terms, whenever they are required for the exposition of new facts or new relations. Considering that the book is likely to be freely used as a source of information by the manufacturers of text-books, who often have no leisure to read original papers, at the same time that they desire to be up to date, it is well for their sakes, and still more for the students for whose use the boiled-down product is destined, that Miss Welby has succeeded in selecting short, simple, and expressive words. What could be better, for example, than her translation of "*ueberwerthig*" and "*unterwerthig*" by "above par" and "below par," or of "*abgeleitete Stelle*" by "lead off." On the whole Miss Welby has given the sense of her author with great care and accuracy, and writes, whenever the responsibilities of translation allow it, in good style. But in thus commending her work, we do not wish it to be understood that there may not be here and there slips to be put right in the second edition—such, for example, as the rendering of the German word *Canüle* by *Canula* (*sic*) (p. 80), or of "*graphische Darstellung*" by "graphic record" (p. 370), or, in the same paragraph, of "Boussole mit möglichst leichtem Magneten" by "galvanometer with a very free magnet"; but even such small errors as these are few and far between.

Cat and Bird Stories. From the *Spectator*, with an introduction by John St. Loe Strachey. Pp. xiii + 279. (London: T. Fisher Unwin, 1896.)

STORIES of animal intelligence are interesting, and they are of value in considering the relations between habit and instinct, and the question of reasoning power, when they can be trusted. But accurate observers are few, and sentiment often causes a simple fact to be buried in anthropomorphic imaginings, so that stories have to be taken *cum grano*, and the identity of the writer must be known before their scientific value can be appraised. We must, therefore, demur to the author's remark that "the bird and other stories in the present volume . . . have a distinct scientific as well as a literary value. They are not merely good reading, but the record of important facts in Natural History." Many of the letters are, however, anonymous, and they have been reprinted without asking permission of the writers. No man of science would have the temerity to cite irresponsible anecdotes from a collection got together in this way, as evidence of animal intelligence. The stories are no doubt entertaining, but the less that is said about their scientific value the better will naturalists be pleased.

The sub-title of the volume is worth preserving. It states that to the cat and bird stories are added "sundry anecdotes of horses, donkeys, cows, apes, bears, and other animals, as well as of insects and reptiles."

Handbook of Courses open to Women in British, Continental, and Canadian Universities. Compiled for the Graduate Club of Bryn Mawr College. By Isabel Maddison, B.Sc., Ph.D., assisted by Helen W. Thomas, A.B., and Emma S. Wines, A.M. Pp. iv + 155. (New York: The Macmillan Company.)

THE need of a handbook defining the position of universities in regard to the admission of women to their courses, has been strongly felt ever since the movement for the higher education of the gentler sex began. In the volume before us the need is admirably supplied. From the book, women graduates who desire to continue their studies abroad, and students who wish to know where they can attend courses and where receive degrees, can derive all the information they require as to methods of admission, cost of living, names of professors and lecturers, &c. It will be to women what the invaluable "Minerva Jahrbuch der gelehrten Welt" is to every one desiring information on institutions for higher education.

We notice that Queen's College, London, is omitted (though it has a charter), while King's College is included. As it is proposed to publish a new edition annually, the omission may be put right in the next issue.

Ostwald's Klassiker der Exakten Wissenschaften, Nos. 76–79. (Leipzig: Wilhelm Engelmann, 1896.)

PROF. OSTWALD'S reprints of physical classics are too well known to need recommendation. Four volumes have recently been added to the series, viz.:—

No. 76: "Theorie der doppelten Strahlenbrechung, abgeleitet aus den Gleichungen der Mechanik," by F. E. Neumann (1832), edited by A. Wangerin.

No. 77: "Über die Bildung und die Eigenschaften der Determinanten," by C. G. J. Jacobi (1841), edited by P. Stackel.

No. 78: "Über die Functionaldeterminanten," by C. G. J. Jacobi (1841), edited by P. Stäckel.

No. 79: "Zwei hydrodynamische Abhandlungen." (1) "Über Wirbelbewegungen" (1858). (2) "Über discontinuirliche Flüssigkeitsbewegungen" (1868), by H. Helmholtz, edited by A. Wangerin.

The editorial remarks are very full in each case, and they add to the value of a unique series of republished scientific papers.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Production of X-Rays.

OBSERVERS who use Wimshurst machines should remember that part of their difficulty in obtaining X-rays with a steady current and low vacuum may lie in a peculiarity of the machine itself, viz. that it will not work well when short-circuited. Machines with permanently charged armatures do not suffer from this defect, though certainly it does appear that a given quantity delivered in jerks is optically more effective than the same quantity delivered smoothly. But this seems to be a physiological rather than a physical fact, because I do not find it true photographically. The easiest plan to get a jerky current is to use what I have elsewhere called a B-circuit—attachments to outside of jars,—and the bulb is then, as Mr. T. C. Porter says, almost objectionably brilliant. OLIVER J. LODGE.

Responsibility in Science.

UNDER the above heading, Mr. C. Chree wrote to protest against some remarks in my address to Section D of the British Association, which met recently at Liverpool. Having only just returned to England, this is my first convenient opportunity of replying to his letter, which appeared in NATURE of October 15 (p. 572).

Mr. Chree objects to the view that "physicists as a body" have accepted Lord Kelvin's and Prof. Tait's conclusions as to the age of the earth. In a matter of such great importance and interest, and one which has courted criticism for so long a time and on occasions of such exceptional prominence, it is probably fair to conclude that, with the great majority of physicists, "silence gave consent." Furthermore, many distinguished physicists have expressly told me that they could find no flaw in the case.

If Lord Kelvin and Prof. Tait express a strong opinion, if this opinion is quoted again and again, and is only criticised by geologists and zoologists, no physicist saying a word, it is likely enough that the geologist and zoologist may come to entertain an exaggerated notion of the amount of support conceded to the opinion by the whole body of physicists.

The point does not seem to me to be a very important one; and I do not imagine that "physicists as a body" will be much aggrieved because I assumed that they agreed with Lord Kelvin on this point.

Mr. Chree then proceeds to impute to me various opinions which I do not hold, and supports the imputation by finding, in my address, a "strong flavour" of views which only exist in his imagination, or by asking whether I believe some opinion which I never expressed, and which he then goes on to demolish.

Thus, I never said, or implied, or believed that "a solid is *rigid* in the mathematical sense," or that "electrical and thermal conductivity necessarily . . . vary together." I understand that Prof. Schuster's conclusion as to the high internal electric conductivity *suggests* a high thermal conductivity, and no more than this can be got out of my address; and this, I have reason to believe, is an opinion shared by Prof. Schuster himself, and probably by the majority of physicists.

The author also takes some pains to show that other forces besides the tides have influenced the rate of the earth's rotation. He might have spared himself the trouble. I was not writing a treatise on the subject, but attempting to give an account of Lord Kelvin's views, and Lord Kelvin considers the tides to be all-important in this respect. He considers and dismisses as comparatively unimportant the agencies alluded to by Mr. Chree.

The evidence from the mean density of the earth was never put forward as conclusive, but only as suggestive.

I can only account for the remark that I "might be well advised to allow for the possibility that Lord Kelvin's speculations do not possess a monopoly of physical uncertainties," on the hypothesis that Mr. Chree has not read my address carefully, or has failed to comprehend the attitude I assumed. I all along recognised the "physical uncertainties" on every side, and made no claim whatever to replace them by certainties. My whole object was to show that no certain conclusions can be reached

from physical data, and that we, the geologists and zoologists, "are free to proceed, and to look for the conclusions warranted by our own evidence."

Lord Kelvin's experiments on thermal conductivity of rock at various temperatures are of the highest interest. I did not allude to them because it seemed to me unnecessary to point out that, until we know the nature of the material which forms the deeper parts of the earth, any attempt to generalise from the results of experiments on the material of the surface must be inconclusive.

Mr. Chree thinks that I might have made something of the uncertainty as to the true mean temperature gradient at the surface. The reports of the British Association on underground temperature afford abundant support for a temperature gradient in the northern hemisphere, which cannot be very different from that selected by Lord Kelvin.

I fail to grasp the object of Mr. Chree's letter, unless it be to proclaim that he never accepted Lord Kelvin's conclusions, and I cannot see that any great object is gained by even this statement.

As I am writing on the subject, I should wish to point out that the address, as printed in the Report of the Liverpool meeting, will be slightly different from that which has appeared in the columns of NATURE. Lord Kelvin kindly drew my attention to one or two errors which will be corrected in the Report.

Oxford, November 20. EDWARD B. POULTON.

Measurements of Crabs.

I AM much obliged to Prof. Weldon and Mr. H. Thompson for the careful consideration they have given to the doubt which I raised concerning the validity of the comparison made by the latter of measurements of crabs collected from the same locality in different years. Prof. Weldon offers some evidence to show that immersion in spirit does not affect the relative dimensions of parts of the carapace. The evidence is not direct, nor perhaps is it complete. It refers to female crabs, and not to the male specimens with which Mr. Thompson was dealing. But I notice that according to Prof. Weldon's measurements the spirit specimens of 1895 differed more than the fresh specimens of 1895, from the spirit specimens of 1893, whereas if the spirit were the cause, the difference would be less between spirit specimens and spirit specimens than between spirit specimens and fresh specimens. I admit then that there is little possibility of the observed difference being due to the action of spirit.

But Mr. Thompson's letter suggests other reflections. He draws my attention to the fact that the difference which he observed between crabs of the one year and those of the other, is of precisely the same kind as the difference between an older crab and a younger crab, or rather between a larger crab and a smaller crab. As the male crab increases in size, its frontal breadth is continually becoming less in proportion to its carapace length, while its dentary margin is becoming greater. What Mr. Thompson found, therefore, was simply that in one sample the individuals of a given size were more advanced in development than those of the same size in the other sample. The development or law of growth remaining the same, the size of one sample had been reduced in comparison with that of the other. But this is not, I think, correctly described as a change in the character of the species. I find that the crabs of the same stage from the two samples differed in average length by about '5 mm., which is a very small difference. Such a difference might well be caused in the young crabs of two different seasons by a difference in abundance of food, due to meteorological differences; the crop of young crabs was finer in one season than in the other. I believe that if the lambs of two seasons were compared in the same way, differences in the rate of growth, or in the size of the individuals which had reached the same stage of development, would be found. We may say, indeed, that such differences are known to be of general occurrence. Mr. Thompson's paper suggests that a considerable change in the proportions of parts characteristic of the *species* had been observed, whereas, in point of fact, no new proportions were observed at all, but the old were found to be present in individuals of different sizes. J. T. CUNNINGHAM.

College of Surgeons, November 20.

Suggested Reef Boring at the Bermudas—and elsewhere.

MR. W. K. MORRISON'S suggestion (NATURE, November 5) of the Bermudas as a site for renewed reef-boring experiments, and for the establishment of a permanent biological observatory is well worthy of consideration. It is, at the same time, desirable to remark that the Bermuda reefs scarcely appear to possess the most favourable conditions for boring operations. As long since recorded by Dana ("Corals and Coral Islands," p. 361), the Bermuda coral rock abounds with caverns and fissures, and there would consequently be an imminent risk of negative results being obtained there, as has happened at Funafuti, through the uncontrollable infiltration of sea-water. The circumstance, also attested to by Dana, that the reef-making species of corals at the Bermudas are but few in number, and are constantly submerged to a depth of from, at least, one to four fathoms, places this island group, as a station for the especial investigation of coral-growths, at a disadvantage in comparison with many others that might be mentioned.

Much might be written in favour of the many locations on the Australian Great Barrier Reef that would be particularly suited for the prosecution of the borings and biological investigations proposed. My later sphere of investigation has brought within my notice another area which, in certain respects, offers advantages and facilities possessed by no other spot throughout the coral regions with which I am acquainted. I refer to Houtman's Abrolhos, lying thirty miles to the westward of the port of Geraldton, within a day's journey from Perth, on the coast of Western Australia. A paper indicating certain of the more remarkable marine biological features of these islands was communicated by me to last year's Ipswich meeting of the British Association, and the subject is dealt with in further detail in a chapter of my book, "The Naturalist in Australia," now on the eve of publication. The data recorded that are most pertinent to the present issue are as follows.

Notwithstanding the position of the Abrolhos islands so far south, 28° to 29°, as to be outside the limits of the tropics, the marine fauna—owing to a warm southerly drifting equatorial current—corresponds more nearly in character with that of Torres Straits than with that of the adjacent mainland coastline as far north at least as King's Sound, in latitudes 16° to 17°. The western is a perfect archipelago of coral islands, including lagoon, barrier, and fringing reefs, and abounds with readily accessible coral growths in infinite variety.

An abundant illustration of what Houtman's Abrolhos can produce is afforded among the series of coral specimens from the Western Australian reefs, recently contributed by me to the British Museum coral galleries.

Any practical scheme initiated in this country having as its object experimental reef-boring, or the establishment of a marine biological observatory on Houtman's Abrolhos, would undoubtedly receive substantial sympathy and support at the hands of the Western Australian Government collectively, and yet more definitively through the medium of its far-seeing and scientific-minded Premier, Sir John Forrest.

Any assistance towards the furtherance of this suggested scheme, should it merit consideration, that may lay within my power, would be most willingly contributed.

London, November 9. W. SAVILLE-KENT.

The Structure of Nerve Cells.

THE Spanish histologist, Dr. S. R. Cajal, on p. 9 of his book "Les nouvelles idées sur la structure du Système nerveux," translated into French by Dr. L. Azoulay, makes the following assertion:—"Les cellules nerveuses sont des unités indépendantes, ne s'anastomosant *jamais* ni par leurs rameaux protoplasmiques, ni par leurs expansions nerveuses ou cylindres axes." (The italics are mine.) I venture to bring this statement forward because recently I have discovered that it is not universally correct: in sections of the medulla oblongata of a young snake, *Tropidonotus natrix*, prepared according to Cox's modification of Golgi's corrosive sublimate process, I have found a pair of cells on the ventral edge distinctly united together by a protoplasmic process, or, as I would propose to term it, a dendrite. Cox's mercurial method is so far better than the chrom-osmium-silver method, inasmuch as the preparations made by it keep much longer. ALFRED SANDERS.

The Hawthorns, Caterham Valley, November 26.

Snow Buntings.

IT may interest some of your readers to learn that on November 17 I saw near the top of Snowdon a flock of snow buntings. The mountain was snow-clad, and had been so for several weeks. J. R. DAKYNS.

Penn-y-ywyl, November 23.

BOOKS ON MOUNTAINS.[1]

DURING the last forty years we have had many books on Alpine climbing, as Mr. Baillie-Grohman observes, but not one on Alpine sport; for the late Charles Bonar wrote his delightful little volume on "Chamois Hunting" before the first Alpine Club was founded. That, however, dealt with a rather limited portion of the Alps, and was chiefly concerned with the chamois, though it also gave some account of stag shooting. Mr. Baillie-Grohman takes a wider range, both of space and of subject. Still, even he writes mainly, as did Mr. Bonar, of the Bavarian and Tyrolese Alps; indeed, the Graians are the only district that receives more than a casual notice. The reason for this is obvious; in the Central and Western Alps the red deer is unknown, and the chamois, as a rule, is not common. The latter, indeed, might have followed the former; for republican principles, as all the world knows, are not favourable to the preservation of game; but the Swiss authorities, whether actuated by sentiment or by an eye to the main chance, have taken steps—and with considerable success—to save this animal from extermination. But in the limestone range which lies north of the Inn, on the frontier of Bavaria and Austria, and in one or two parts in the main range of the Tyrol, there are large mountain

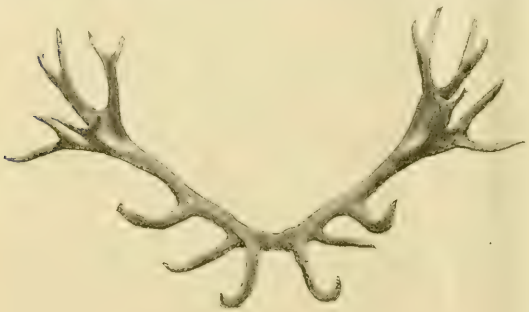

FIG. 1.—The largest Red Deer Antlers in existence.

districts which are strictly preserved by their owners. One of these districts, as Mr. Baillie-Grohman says, might be called "the Dukeries," for all its masters are at least of that rank; the finest "shoot" belonging to Saxe-Coburg-Gotha. Mr. Baillie-Grohman tells many interesting anecdotes of the late Duke, one of the keenest of sportsmen, whose shooting party he was frequently invited to join.

The book, of course, is written for sportsmen, and is to a considerable extent occupied with the author's own experiences, his successes, and disappointments; but he also gives many particulars of the chase in bygone times, which are illustrated by reproductions of some quaint old pictures. But he incidentally brings in some matter interesting to the naturalist. Mr. Baillie-Grohman of course has much to say on the horns of the quarry—the chamois, the red deer, the roe deer, and the bouquetin—and he gives details of the growth and of other peculiarities, with illustrations of horns notable for size or for singular deformities. An exceptionally large pair are represented in the annexed illustration (Fig. 1), for the use of which we are indebted to the publishers. These appendages often exhibit slight differences depending on locality. According to the author, the horns of chamois from the crystalline districts of the Alps run a little smaller than those from the calcareous; but besides this, slight differences in form are exhibited in places widely apart, and this is yet more strongly exemplified in the case of the chamois of the Alps and the izzard of the Pyrenees. The horns, also, of the Alpine stag considerably exceed in size those of the Scotch red deer. This subject is discussed at some length, Mr. Baillie-Grohman bringing forward evidence to show that the growth of the horns depends, among other circumstances, upon the food supply, and that the size of the antlers is affected in any one year by the nutriment of the stag during the period when these were growing. The Scotch antlers, he says, are comparatively small, because the food supply is insufficient and irregular; "the survival of the fittest" is not properly secured, and the improvement of the breed is neglected. The continental sportsman cares most for the antlers, the British for the venison, or simply for the number of the slain, so that the quality of the stag is deteriorating in the so-called forests of Scotland. The chase, by the way, in the Alpine regions takes place in actual forests, and the quarry is stalked during the rutting season, when the stag betrays his situation by his roar, and is forgetful of danger while on amorous thoughts intent. The roe deer is abundant in the north-eastern Alps, and is a plucky little animal; but the bouquetin or steinbock is now restricted to the Graian Alps, though formerly it ranged over every part. It finally disappeared from the Pennines about the middle of the present century, and would have been exterminated in the Graians by now had it not been taken under royal protection. This animal does not appear to have fallen to the author's bullet. For the details of all these and other matters we must refer to the book itself. It is well printed and well illustrated, full of interesting details of the chase and anecdotes of sport; it is redolent of the perfume of the forests and the clear air of the mountain peaks; it is the work of a ready writer, and of a lover of the Alps.

Dr. von Lendenfeld's work might be called a version of "The Alps from end to end," adapted to the ordinary traveller. It is neither a guide-book nor a systematic treatise, but it consists of a series of sections or short articles, describing all the most interesting and characteristic districts of that great mountain chain, from the shore of the Mediterranean to the neighbourhood of the Semmering Pass. There is no preface, so that we are not informed how far the book is the result of the author's personal experience, and how far a compilation; but if in any parts he has drawn upon the experiences of others, the tale is told so as to make them seem his own. We can vouch from personal knowledge for the accuracy of some drawings of not very accessible places, such as the sketches of certain high peaks; so that the artist, at any rate, must have been on the spot. The stories of mountain climbs, one or two of which are introduced into each article dealing with the chief Alpine centres, are suc-

[1] "Sport in the Alps in the Past and Present; an Account of the Chase of the Chamois, Red Deer, Bouquetin, Roe Deer, Capercaillie, and Black Cock, with Personal Adventures and Historical Notes, and some Sporting Reminiscences of H.R.H. the late Duke of Saxe-Coburg-Gotha." cinctly and pleasantly told. There is some history and some science, but not too much for the ordinary tourist. Alpine geology, of course, is not forgotten; but here, as the author has had to rely on the work of others, the statements sometimes are open to question. The following may be taken as an example: "Wie am Splügen durchsetz auch am Bernhardin die Trias das Urgebirge des Hauptkammes." But the infolds in the gneissic *massif* on these two passes are crystalline rocks, varying usually from marble to darkish calc-mica schists. They are identical with rocks which elsewhere are indubitably very much older than the Trias, and are about as unlike as they can be to any rock which can be proved to belong to this system. In fact their Triassic age is only a "pious opinion," and, like many such, has no scientific foundation. But the Swiss geological surveyors have not distinguished themselves in the district of the Hinter and Vorder Rhein.

The illustrations are numerous and varied; sketches of characteristic incidents of travel, such as scenes in an hotel, at the station of a mountain railway, in a market-place or at a *fête*; views by the wayside, groups of châlets, or bits of old architecture, churches, castles, villages, or towns. With these are numerous examples of Alpine scenery, ranging from some little wayside nook to one of the snowy giants of the chain. Many of the former are admirably done; the latter (the scenery) are more unequal. Some, such as the full-page view of the Matterhorn (by Mr. Compton), are very effective, but in others the artist has failed to catch the character of the rocks, and they are merely conventional. Another fault may be noticed, which is becoming too prominent in modern sketches—namely, a tricky disposal of the lights and shadows, which produces a "splashy" effect, and an exaggeration of the features of the scenery, so that nature is caricatured rather than depicted. Still, though the style which illustrated journals have fostered is occasionally too prominent, the pictures are remarkably good, and exceed in quantity and quality what we should get in a book of similar price "made in England." It forms a very agreeable souvenir of the Alps, for its pages will recall pleasant memories to every tourist. So attractive indeed is it, both in illustrations and in text, that we hope the publishers will have it translated, for an English edition ought to find many purchasers in this country.

In his book on Chamonix Mr. Whymper has endeavoured, as he says, "to give in a small compass information which some may desire to have at home, and that others will wish for on the spot." Thus, while it contains all that is usual in a guide-book, it gives a good deal more, so that some of the chapters are very interesting reading. One, for instance, is devoted to the early history of Chamonix and Mont Blanc; the one, as we learn from the information which Mr. Whymper has obtained, can be traced back almost for eight centuries, while the other appears not to have acquired its distinctive name until the earlier part of the last century. We read in his pages the tale of the first attempts to ascend the mountain, of Jacques Balmat's success in discovering the route to the summit, of H. B. de Saussure's ascent, and of some of the more interesting of those accomplished by later travellers. Next comes a "chapter of accidents," giving a brief outline of those numerous catastrophes which associate the mountain with so many sad memories. Then follows an account of the attempts to use it for scientific purposes; and the remainder of the book is occupied by descriptions of the means of approaching Chamonix, of the modern village—or town, as now it might almost be called—of the various excursions from Chamonix or the immediate neighbourhood, both small and great, of the different routes to the summit of Mont Blanc, and, lastly, of the "tour" of the mountain. Needless to say that the book is well designed and well

FIG. 2.—The "Aiguille Verte and the Aiguille du Dru."

written, because Mr. Whymper, as we know from his larger books on the Alps and the Andes, can describe as well as he can depict. It is impossible to criticise, when the author stands almost alone in his thorough knowledge of the district. There are illustrations—one of which (Fig. 2) we are permitted to reproduce—plans, and an excellent map of the snowy range. So much is given in a short compass, that it seems greedy to ask for more; but we think that, notwithstanding the full table of contents, an index would be an improvement, and that a few paragraphs on the geology and natural history of the range might be added with advantage.

Mr. FitzGerald's book, as he states, is "a simple record of adventure," but he adds very much to our knowledge of the most interesting districts of the New Zealand Alps, the topography of which is made clear by his excellent map, founded on the latest Government Survey. The Alps of the Southern Island correspond in structure more nearly with the Pyrenees than with their European namesakes—that is, they are a single range rather than a chain consisting of a series of great parallel folds. Though the highest peak, Aorangi or Mount Cook, introduced to the notice of English climbers by the Rev. W. S. Green, attains an elevation of 12,349 feet, not many exceed 10,000 feet. The snow-line, however, is quite 2000 feet lower than it is in Switzerland, and the glaciers descend much nearer to the sea-level. On the eastern side the great Tasman glacier comes down to about 2350 feet; while on the western side, where the valleys are considerably steeper, for the watershed is much nearer that coast, the glaciers descend more than once to 1200 feet, the Fox glacier actually ending about 700 feet above the sea. Yet the mean temperature in the latitude of Mount Cook is about 52°. As the temperature of the Swiss lowland, at an elevation of some 1300 feet, is about 47°, the difference, so far as this cause goes, is not large, and the greater extension of the snow region and descent of the glaciers must be partly due to the heavier rain (or snow) fall. Probably this is something like 150 inches on the higher parts of the western slopes, or nearly double of what it is at corresponding positions in the Alps.

The mountaineer finds the peaks and glaciers of New Zealand in many respects more difficult than those of the "playground of Europe." They are not easily reached, for at present no good roads have been made in the higher valleys; the weather is most unfavourable, often persistently bad, always liable to sudden change; there is one mountain inn in the whole region; there are no châlets, practically no guides or porters. Thus the traveller must bring a guide from Europe, must be prepared to bivouac—under what discomfort readers of Mr. FitzGerald's book will learn—on the mountain side, and to carry his own "swag." "Expensive, laborious, and often disappointing," seems to be the motto of a tour in the high Alps of New Zealand. The climber also has to face considerable difficulties, and even dangers: certainly more on the average than among peaks of corresponding elevation in Switzerland. The rock, in the parts explored by Mr. FitzGerald, is bad slate or slabby greywacke, very incoherent and untrustworthy. He had many narrow escapes, and near the summit of one peak—Mount Sefton—was only saved from a fatal fall by the

FIG. 3.—Fuji-san, with cloud cap, from the South-west.

skill and strength of his guide, Mattias Zurbriggen, and by his own readiness of resource. The accident was caused by the wholly unexpected fall of a great block of stone. Notwithstanding all difficulties, Mr. FitzGerald made the ascent of four peaks hitherto unclimbed—Mount Tasman (11,475 feet), Mount Sefton (10,350 feet), Mount Haidinger (10,054 feet), and Mount Sealy (8,631 feet), and crossed three new glacier passes. One of these, though it hardly deserves the name of a glacier pass, is a discovery of importance to the colony. Till this time the great mountain wall had prevented any communication between the eastern and western coasts except by sea, so that a direct route across this barrier anywhere near the middle of the island was much desired. Mr. FitzGerald discovered a pass, which now bears his name, leading direct from one of the branches of the Tasman valley to the west coast. There is a very small glacier on the east side, and none at all on the other. It is, as he says, a pass comparable with the Monte Moro in Switzerland, and so, with some expenditure on making the track, may be easily crossed by packhorses and cattle, at any rate during the summer season. His own experience was the reverse of agreeable. Preliminary explorations with Zurbriggen showed them that the eastern side presented no difficulty, and suggested that the descent on the western would be easy. So it was for a while; then they found themselves confronted with an impenetrable "scrub" at a place where the river entered a gorge. After attempting the former, they were forced to follow the latter as the less evil way. But the result was that, instead of reaching the west coast in about twenty-four hours from the starting-point, they were out for two nights and nearly three days, having taken provisions for one day only! This difficulty of course will not recur, for a road can be easily cut through the scrub. The book is well written and illustrated, though perhaps one or two of the pictures —*not* made from sketches taken on the spot—are slightly sensational. Some appendices contain details of interest as to geology and natural history. It tells unaffectedly and most attractively a tale of careful preparation, bold climbing, and wonderful endurance.

Mr. Weston, while British chaplain at Kobe, spent his holidays for four years in wandering about the mountain regions of Central Japan. Of course he was often far away from beaten tracks, and saw much of the native life in its original simplicity. His experiences are described in the brightly and pleasantly written volume before us, which also contains some curious information as to the customs and the religious beliefs of the people, demonology, the "possession" of human beings by animals, ghosts, rites of incantation, such as those for affecting the weather, and the like. He seems to have found no special difficulties in travel, and generally met with a kindly reception from this quaint and courteous people, except once or twice when impediments were caused in regard to passports, or from a belief like that which formerly kept the Swiss away from Pilatus; but he had often to rough it, for the accommodation frequently is very primitive, and food is scanty. But there is one set-off in Japanese travel, that the "honourable hot-bath," as it is politely called, is a general institution. As, however, this serves many bathers without change of the water, it is well to secure an early turn.

The backbone of the Japanese Alps consists of granitic rocks with crystalline schists, through which igneous masses have been extruded. Thus some peaks are of granite, others are of felstone or old volcanic rocks, others are cones which still retain their craters. Hence the rocks are of very different ages, and some of the older exhibit marked indications of mechanical disturbances. The higher summits seem very commonly just to overtop 10,000 feet. Thus Hodakadake, the highest granitic peak in Japan, is 10,150 feet; Yarigatake, the boldest in outline and a "brecciated porphyry," is 10,300 feet; while Fuji-san, which exceeds all the rest by 2000 feet, being 12,400 feet, is a crater. This indicates considerable difference in age, and the chain very probably is of a complex character. Mr. Gowland, who contributes a few remarks on the geology, thinks its beginning was in Palæozoic times, when it consisted chiefly of granite and schists. All the above-named peaks and sundry others were ascended by Mr. Weston, who also crossed several passes. These generally range from about 5000 to rather more than 7000 feet. In fine weather the climbing does not seem to present many serious difficulties, but the great rock slabs are apt to be slippery in wet, and the distances traversed on foot are sometimes rather great. His verdict is that while these mountains do not display the glory of glacier-shrouded peaks, and are on a scale only two-thirds of the Alps of Switzerland, they surpass anything he has met with among the latter in "the picturesqueness of their valleys and the magnificence of the dark and silent forests that clothe their massive flanks." The larger illustrations show that this praise is not exaggerated; two of the most striking represent the granitic pinnacles of Hodakadate and the singular cone of Fuji-san capped by a "bonnet cloud." For the use of the latter illustration (Fig. 3) we are indebted to the publishers. The smaller cuts also, which represent a variety of subjects, and are in several cases excellent, add to the value of this attractive work.

T. G. BONNEY.

OYSTER CULTURE IN RELATION TO DISEASE.

UNDER the above title the Medical Officer of the Local Government Board has just issued a supplement to his report for 1894–95, dealing with reports and papers on the cultivation and storage of oysters and certain other edible molluscs in relation to the occurrence of disease in man. An inquiry on this subject was bound to be instituted sooner or later. There has been an uneasy feeling for many years past that the infection of enteric or typhoid fever is at times due to the consumption of uncooked oysters; and in his report on cholera in England in 1893, Dr. Thorne Thorne expressed his conviction that the distribution of shell-fish from Cleethorpes and Grimsby, as a centre, had been concerned in the diffusion of scattered cases of cholera over a somewhat wide area of England, owing to the fact that oysters and other molluscs at these ports were so deposited and stored as to be almost necessarily bathed each tide with the effluent of sewers at that time receiving cholera discharges. In the early part of 1895, Sir William Broadbent also publicly announced his conviction that oysters were occasionally capable of transmitting the infection of typhoid fever, and the fact received startling confirmation from a report to the State Board of Health of Connecticut, U.S.A., by Prof. Conn, on an oyster epidemic of typhoid at Wesleyan University, Middletown, Connecticut, in which some twenty-six cases of that disease were indisputably traced to the consumption of raw oysters, which had the opportunity of becoming specifically contaminated by sewage delivering at the time the discharges of typhoid patients. A similar outbreak of Saint-André de Sangoins, in the Mediterranean Department of Herault, was investigated by Dr. Chantemesse, and traced to oysters received from Cette, on the coast of the same Department, where, according to a Commission subsequently appointed, the oysters had been stored in waters highly contaminated with sewage.

Under these circumstances, the Local Government Board determined to institute a searching inquiry into the conditions of oyster cultivation and storage along the coasts of England and Wales, and to cause bacteriological investigations to be made as to the power of the

oyster to absorb, retain, and transmit the typhoid bacillus and the cholera vibrio. The first part of the inquiry was entrusted to Dr. Timbrell Bulstrode, and the second portion to Dr. Klein. Their reports, which are suitably illustrated with photographs and maps, constitute the material on which Dr. Thorne Thorne bases his introductory remarks. In the appendix are given a copy of Prof. Conn's report already alluded to, and an extract from the *Proceedings* of the Académie de Médicine in Paris, relating to the spread of disease through the agency of oysters.

The value and extent of the oyster trade in this country may be gleaned from the following figures, furnished by Dr. Bulstrode. In 1894 there were landed on the English and Welsh coasts, by English dredgers, 27,747,000 oysters, valued at £84,271, the average price being per 100, 6*s.* 1*d.*, and per 1000, £3 0*s.* 10*d.* These were delivered on the several coasts as follows :—

	Oysters.		Value.
East Coast ...	16,833,000	...	£58,300
South Coast ...	4,251,000	...	11,186
West Coast ...	6,663,000	...	14,785
	27,747,000	...	84,271

These figures relate only to oysters landed by English boats employed in the home industry; in addition enormous quantities are imported from abroad, partly for relaying, and partly for more or less immediate consumption. American oysters, known as "Blue points," "East rivers," and "Sounds" are mainly received at Liverpool and Southampton, whilst the Dutch and Belgian oysters chiefly come to Grimsby and Brightlingsea. A considerable number also are received from Scotch and Irish beds.

It is generally assumed, at all events, by the more educated lovers of the bivalve, that oysters are "out of season" during such months as have not the letter "r" in their names, and as a matter of fact the "close time" for oysters, born and bred in this country, extends from May 14 to August 4—that is during the spatting season. But that portion of the community which is referred to in the report as "the less fastidious class," and which is "addicted to the practice of sea-side trips of brief duration," is addicted also to the practice of eating the oyster at any time of the year it can be got, and in the summer months, therefore, has to content itself with the imported varieties, the restriction as to "close time" not applying to oysters taken in the waters of a foreign State.

It would appear from the returns that the largest number of oysters is consumed in September; but, although the number eaten diminishes as the year draws to a close, their value steadily increases up to December, when it gradually diminishes, month after month, until it reaches a minimum in June or July.

As the result of Dr. Bulstrode's inquiries and observations, it is distinctly disquieting to be told that only a few of the oyster layings, fattening beds, or storage ponds round the English and Welsh coasts can be regarded as theoretically free from every possible chance of sewage pollution. At the same time, in the case of the majority of them, the polluting matter is mixed with so vast a bulk of water that there is little substantial risk of deleterious influence. The possible mischief is due to the circumstance that the cultivation of the oyster is mainly carried on at points on the coast which are readily accessible, and where labour can be easily obtained, or, in other words, in tidal estuaries in the neighbourhood of more or less populous places, into which, therefore, the sewage of such places is apt to be delivered. In the report, three such localities are singled out for special condemnation; viz. Southend, where, as regards one laying, "the sea-bottom and the matters floating on the surface, afford the most obvious proof that the conditions are filthy in the extreme"; at Cleethorpes, where the layings are exposed to the influence of sewer outfalls, serving (counting that of Grimsby) populations of about 67,000; and the Medina, in the Isle of Wight, of which it is stated that "it seems almost beyond comprehension how any one could venture to 'fatten' oysters for human consumption in a river estuary such as this, which is fouled above the layings by the crude sewage of Newport, with its 10,000 inhabitants, by the effluent from the neighbouring prison and barracks, and by the overflow from the workhouse cesspool; and which receives into it immediately below the layings the contents of eight other sewer and drain outfalls from East Cowes and West Cowes." It is further pointed out that "the layings in the Penryn River, Cornwall, and those in Brightlingsea Creek, in Essex, also call for especial notice in connection with the obvious risk of sewage pollution. At Brightlingsea this risk has more than once been drawn attention to by the local health officer. The layings in the South Channel, off Southwick, near Shoreham, are similarly exposed to sewage; and in a minor degree, on account of the great bulk of water there in question, such layings as those in the Menai Straits come under suspicion. From most, if not all, of these layings, oysters are despatched direct to market."

On the other hand, some of the most celebrated layings on the coast of Essex and Kent—as in the Crouch, Roach and Blackwater, and off the Swale—are practically free from risk, although the layings in the bed of the Colne which presumably furnish the supplies for the time-honoured "Colchester feast," are subjected to the comparatively concentrated effluent of Colchester sewage at low water, and to the additional pollution to which the river is subjected at Wivenhoe and Rowhedge.

The conditions under which the oysters are stored in beds, ponds, or pits, pending despatch to market, naturally received close attention. The layings or "fattening" places might be everything that could be desired, but the oysters, when lifted, might still be stored in a most objectionable manner. The boxes off Southend Pier, for example, float in what is practically dilute sewage. A set of storage pits at the mouth of the Blackwater was found to be within forty-three yards of the point at which the drainage of twenty houses is discharged. At Wivenhoe "it is impossible to see how the oysters there stored in pits can escape contamination by sewage." The means for the storage of oysters in the Fish Dock at Grimsby, are stated to be particularly offensive and dangerous. "It would be difficult to find much worse conditions than those under which certain storage pits are placed at Poole." . . . "At Warsash, above the junction of the Hamble River with Southampton Water, a sewer was found opening out just between two oyster ponds. Again at Emsworth, near Havant, a sewer and certain drain outfalls have been conveyed into the middle of a group of oyster pits, and matters are little better at Bosham."

On the other hand, the methods of storage on the Crouch and Roach, and for the most part also of the Blackwater, leave little to be desired, and the same may be said of the layings and means of storage in the Helford River in Cornwall, and at Newtown Estuary in the Isle of Wight.

To judge, however, from the frequency of instances to the contrary, it would almost seem that the cultivators were under the belief that the oyster actually enjoys himself and waxes fat in insanitary surroundings. Precisely the opposite is the case. No one enjoys the confidence of the oyster to a greater extent than Prof. Herdman, or is better able to appreciate his innermost sentiments; and we gather from Prof. Herdman's recent work that the oyster—especially the British-born-and-bred oyster—is, in reality, a cleanly, self-respecting mollusc, with an appetite not less dainty or fastidious than that of the epicure for whose gustatory pleasure he

is supposed to live. Indeed, if oysters in general had only the locomotive powers of their brethren in the classical legend of the Walrus and the Carpenter, there is very little doubt that, in many cases, they would quickly move off in search of quarters more salubrious than those in which they are often compelled to exist.

It is not easy to indicate how the present condition of things may best be remedied. Oysters, of course, are not a necessity, unless to the hardly-driven brain worker, to persons of feeble digestion, or to convalescents. Unless something is done, therefore, to reassure the public mind—either by the collective action of the oyster breeders themselves, or by systematic inspection on the part of the State—the future of the industry will be seriously jeopardised. As it is, the "scare" has done very great damage to the trade, and the good and the bad alike have indiscriminately suffered. To the statesman who is concerned with the welfare of a littoral population from which the *personnel* of our navy and coast defences is largely recruited, the problem has even a wider and deeper significance. On every ground, therefore, the question calls for prompt remedial action.

At the conclusion of his report Dr. Bulstrode makes some reference to "green-bearded" or "green-finned" oysters. These oysters find but little favour in this country, although, as is well-known, they are much appreciated in France, and the "huitres vertes" or "huîtres de Marennes" obtain a far higher price in the Paris market than the "huîtres blanches." This green colour, which is met with to a small extent in certain Essex oysters, has been the subject of repeated investigation during the last seventy years, notably by Gaillon (1820), Valenciennes (1841), and Puségur and Decaisne (1877). The last-named observers found that the green tint was due to the inclusion of a diatom—*Navicula ostrearia*, or, as it is now called, *N. fusiformis*, taken up from the "claires" in which the oysters are confined. These observations were confirmed and extended, in 1885, by Prof. Ray Lankester, who showed that a blue pigment, which he termed "Marennin" occurs in the *Navicula*, and is either "uniformly diffused throughout the cell protoplasm," or "confined to the ends of the elongated cell body" (Bulstrode). In the oyster the green colouring matter is localised on the surface of the gills and labial palps in "certain peculiar cells of the superficial epithelium." It is the deposition of this blue pigment (Marennin) in the yellowish brown gills which, according to Prof. Lankester, gives rise to the green appearance of the "huîtres de Marennes."

It has been often alleged that this greenness is due to copper, and as a matter of fact copper has frequently been detected in oysters since Bizio, in 1835, first discovered it in the organic substance of the mollusc. Dr. Bulstrode, from time to time, sent the writer of this notice oysters from different localities, and copper was uniformly found in them, although in the Marennes oysters it was present in minute amount only—far less, indeed, than in certain oysters of a normal colour. But there is no question that the greenness of certain oysters, especially of those found in Falmouth and Truro waters, is due to copper. The colour, both in character and distribution, is, however, quite different from that of the Marennes oyster. The green Cornish oyster is unsaleable in this country—at least for immediate consumption—as it leaves a distinct metallic taste in the mouth, similar, it is said, to that due to "sucking a penny." Dr. Bulstrode caused a number of such oysters to be sent to me at different times. On incineration under conditions which precluded the possibility of the introduction of copper, there was no difficulty in detecting the presence of that metal in the ash. Indeed, here and there in the ash were particles of Alexandrine or Egyptian blue, which, as Davy found long ago, is a *frit*, made by heating together soda, lime, sand, and copper. The amount of copper, on the average, was not more than about 0·02 grain per oyster, but as it is obviously caused by the mechanical retention of cupriferous particles, individual oysters might, and indeed did, contain large quantities. On examining the mud of the locality in which such green oysters occur, it was found to contain 0·148 per cent. of copper. On relaying, the green Cornish oyster gradually loses its colour, and also its metallic taste; specimens of such relaid oysters were found to contain only 0·0060 grains of copper per oyster, which is practically the same (viz. 0·062 grain), as that found in Whitstable oysters which had never been green. This amount would seem, therefore, to be normal to the oyster, and to be probably due to the presence of hæmocyanin, first found by Fredericq in the blood of the octopus, and since shown to be present also in many mollusca.

T. E. THORPE.

NOTES.

FOR the last three or four years we have been treated, in the copy of the *Times* appearing after the Anniversary Meeting of the Royal Society, to strictures of the action of the Council of that body. We have not thought it necessary to reply to these at length, because their origin was pretty well known, and the Royal Society is quite capable of taking care of itself. But this year we think the bounds of journalistic decorum have been passed in a leading article in which the regretted retirement of Lord Rayleigh from the Secretaryship is referred to. The *Times* states: "He has taken, . . . the unusual step of declining to sit on the Council, and no one who knows the play of forces within the Society can doubt that his refusal is significant." This sentence is obviously intended to suggest that Lord Rayleigh's resignation of the position which he has so long adorned, and in which his services have been so greatly valued, is due to a want of sympathy with his colleagues or to a want of respect for them. Lord Rayleigh is absent from England, but we believe that we know enough of the Royal Society and of Lord Rayleigh to warrant us in repelling at once, and, in his absence, the insinuation as unfounded, and as quite unworthy of the journal in which it has been allowed to appear.

AT the Royal Society's meeting, last week, the following were elected Foreign Members of the Society:—Prof. Albert Heim, of Zürich, geologist; Prof. Gabriel Lippmann, of Paris, physicist; Prof. Gösta Mittag-Leffler, of Stockholm, mathematician; and Prof. Giovanni Schiaparelli, Director of the Royal Astronomical Observatory of Brera, Milan.

WE announced some time ago the lamentable death of M. Tisserand, the distinguished Director of the Paris Observatory. The French Government, according to the invariable rule, at once applied to the Academy of Sciences, to nominate two men whom they considered qualified to succeed him. They selected M. Loewy and M. Callandreau, the first place being given to M. Loewy, a fully-trained astronomer, who has made his reputation along many lines of research, and who has for many years belonged to the staff of the Observatory. We learn that the Government has accepted this nomination, and that M. Loewy has been appointed Director in succession to M. Tisserand.

LORD RAYLEIGH and Prof. Ramsay have been elected Corresponding Members of the Berlin Academy of Sciences.

M. MICHEL LÉVY has been elected a member of the Section de Minéralogie of the Paris Academy of Sciences, in succession to the late M. Daubrée.

WE notice with much regret the announcement of the death of Dr. Benjamin A. Gould, the distinguished founder and editor of the *Astronomical Journal*.

DR. GILBERT W. CHILD, Lecturer on Botany in the Medical School of St. George's Hospital, and Public Examiner in the School of Natural Science, as well as for the M.D. degree at Oxford, died on Tuesday. The death is also announced of Mr. William Francis Ainsworth, known for his travels and researches in Asia Minor, Mesopotamia, &c.

THE new aquarium of New York City, in Castle Garden Building, of which mention was made in NATURE several months ago, will be opened to the public on December 15. The opening was delayed by the elaborate work of reconstructing the building.

THE total expense of the British Association meeting at Liverpool, defrayed from the local fund, was (it appears from the final report of the Local Committee) 2625*l*. The balance in the Treasurer's hands is about 980*l*., which the Committee has decided shall be invested, and the income therefrom paid to the Liverpool Marine Biology Committee, for use in the publication of *Proceedings* and the prosecution of scientific research. This action ensures that the meeting will have a lasting effect upon local scientific research, as the fund will be made a trust, and the income only used annually in the Liverpool Marine Biology Committee's investigations.

WE learn that the work on the "Ancient Volcanoes of Britain," upon which Sir Archibald Geikie has been engaged for some years, is now all in type. It will form two large octavo volumes, and will be copiously illustrated. Among the illustrations are numerous reproductions of photographs, also of sketches by the author, representing the more interesting or important features in the old volcanoes of this country from the earliest geological periods to the last great eruptions in older Tertiary time. The work will be further accompanied by a series of maps showing the distribution of the volcanic rocks of each eruptive period. It will be published by Messrs. Macmillan and Co., and will probably appear early next year.

AT the fourth Congrès international de Zoology, to be held at Cambridge in September 1898, under the presidency of Sir William Flower, the prize of the Tsar Alexander III. will be awarded for the first time, and that of the Tsar Nicholas II. will be awarded for the second time. The subject to be treated in papers competing for the former prize is "The Ruminants of Central Asia, from the zoological and geographical point of view," and the latter prize will be for "An Anatomical and Zoological Monograph of a Group of Marine Invertebrates." The prizes consist either of a sum of money or a medal of equal value, at the choice of the successful competitors. Memoirs must be sent to the President of the Permanent Committee before May 1, 1898. All zoologists are eligible to compete, except those belonging to the country in which the Congress will be held. British zoologists are thus excluded.

THE British Chamber of Commerce at Alexandria have come to the unanimous conclusion that the adoption of the metric weights and measures in the United Kingdom would be of advantage to British traders in Egypt. Lord Cromer, in forwarding the report to the Foreign Office, remarks that a very general opinion undoubtedly exists in Egypt that British trade with that country would benefit by the adoption of the metric system of weights and measures, and adds that the compulsory introduction of the metric system was strongly urged upon the Egyptian Government some years ago, when it was held that so brusque a change was to be deprecated. On the Egyptian railways, however, and in fact wherever there are Government weighing machines, the metric system has been adopted, and it is hoped that it will thus gradually take root throughout Egypt.

WE learn from the *British Medical Journal* that, on the suggestion of Dr. Nicholson, Professor of Natural History at the University of Aberdeen, the Town Council of Aberdeen agreed some time ago to utilise part of the buildings of the old bathing station as a marine aquarium. The tanks have been made, and the further necessary fittings are in hand. In view of the great importance of the fishing trade at Aberdeen, further developments have been contemplated with regard to combining a department for fish hatching and culture on a scientific basis with the aquarium. It is to be expected that the investigations carried on in such an institution should prove of great interest and importance to the students of zoology at the University.

THE juvenile lectures at the Society of Arts will this year be given by Mr. Clinton T. Dent, past president of the Alpine Club. Mr. Dent has taken for his subject "The Growth and Demolition of Mountains." The lectures will deal mainly with the destructive agencies, weather, frost, glacier movements, avalanches, waterfalls, floods, &c. They will be delivered on January 6 and 13.

AN advertisement inviting applications for the position of Macleay Bacteriologist to the Linnean Society of New South Wales, Sydney, has lately appeared in NATURE. It may be of interest to state that the salary attached to the post arises from a sum of £12,000 bequeathed by Mr. William Macleay, whose total benefactions to science in New South Wales amounted to about £100,000. In making the appointment the object in view is entirely the advancement of natural knowledge by research, the Linnean Society not deriving any pecuniary benefit therefrom.

M. A. A. L. TRÉCUL, whose death, at the age of seventy-eight, we announced on November 5 (p. 11), was one of the highest authorities on vegetable organogeny. In addition to a monograph of the Artocarpaceæ, he had contributed, during a period extending over half a century, a very large number of papers on various points in the anatomy of plants to the French botanical journals. Among the subjects thus treated of are adventitious roots and buds; the increase in diameter of woody dicotyledons; the origin and development of the fibres of the xylem and phloem; the theory of the graft; the formation of leaves; secondary formations in vegetable cells; laticiferous vessels, &c. His latest observations, contributed to the *Comptes rendus* of the French Academy, were on the ultimate ramifications of the vascular bundles in leaves and petals.

ON Friday last, at a meeting of the full Committee formed to establish an international submarine telegraph memorial, the report of the Executive Committee was received and adopted. The following are the resolutions: (1) That a bust of the late Sir John Pender, at a cost not to exceed 500*l*., be erected in the Imperial Institute or other suitable place; (2) that a sum of not less than 5000*l*. be placed in trust with the Council of University College, London, to form an endowment fund for the maintenance of the electrical laboratory in that College, on the condition that the Council name the laboratory the "Pender Laboratory," and the existing chair of Electrical Engineering the "Pender Chair of Electrical Engineering"; (3) to endow a scholarship, or a scholarship and medal, in connection with electricity at Glasgow. The Lord Provost of Edinburgh desired the word "Edinburgh" substituted for "Glasgow" in the third resolution. This was not done, but the Chairman (the

Marquis of Tweeddale) said, if the funds permitted, the claims of Edinburgh would probably be considered by the Committee. Subscriptions will be invited to carry out these resolutions.

DR. BAUMANN, whose death we announced last week, was professor of medical chemistry at the University of Freiburg in Baden. He was (says the *Lancet*) the son of a chemist, and served the full period of a pharmaceutical apprenticeship, after which he entered the Technical College of Stuttgart in order to complete his studies in chemistry, physics, and natural science. In Tübingen, where he went to take his diploma, the celebrated physiologist, Hoppe-Seyler, recognised the great talent of the young man, and not only made him his assistant, but when Prof. Hoppe-Seyler had been elected to the professorship at the University of Strassburg in Alsace, in 1872, Baumann accompanied him thither. In 1879 he was made director of the chemical department of the new Physiological Institute of Berlin, and in 1882 he became ordinary professor of medical chemistry in Freiburg, where he remained till his death on November 2. Prof. Baumann's work included researches on the subject of metabolism and on cystin. He was the discoverer of the specific action of sulphonal and trional, and also of the presence of iodine in the thyroid gland, this last being one of his latest and most notable achievements. He was only forty-nine years of age at the time of his death.

MR. S. STAINER sends us a further communication on his observations of swallows at Southampton, up to the end of November. He saw these birds on twelve separate days, from November 6 to November 25, the highest number (ten) occurring on November 12, and the lowest (one) on November 25. The weather for the first three weeks of last month was very mild, and it is suggested that during that period the insects upon which swallows feed were present in the air. The east wind, which prevailed during the last week of the month, may have so reduced the food supply as to force migration upon the birds.

AT the Royal Societies Club on Monday, Dr. John Murray, F.R.S., editor of the "*Challenger* Reports" and naturalist on the expedition, was presented by the contributors to the various sectional reports, with an album containing their portraits. The album is a very handsome volume bound in morocco, with illuminated address and dedication plate designed by Mr. Walter Crane. It contains eighty-six portraits. The *motif* of the design adopted for the cover is deep-sea and other animals collected by the expedition. The chair was taken by Sir Clements Markham, K.C.B., F.R.S. (President of the Club), and the presentation made by the Rev. T. R. R. Stebbing, F.R.S.

ALL who have attempted to determine a miscellaneous collection of fossils from any geological formation have soon discovered the difficulty of affixing correct names to all the specimens, and if they have been doing this work with the object of publishing some paper, either dealing with the stratigraphy of a district, or attempting to correlate geological horizons in different parts of the world, they have probably given the task up in despair. A few, no doubt, have been fortunate in possessing friends, whose knowledge of particular groups of fossils could be drawn upon. But it is not always that one knows the best person to apply to, or that one can be certain of a favourable reception. *Natural Science*, in its December number, has published a list of twenty-six specialists who are willing to determine various groups of fossils from various strata, when requested to do so for purposes of publication, and this enterprising action will doubtless be welcomed by many local geologists. We hope that this list is only a first instalment, for there certainly appears to be a large number of groups of fossils in which no one is prepared to pose as an authority. We should have thought that some one might have been found for the trilobites, the belemnites, or the palæozoic brachiopods. Obviously, if any one wishes to take up the study of some special division of palæontology, he need not be deterred by the lack of an opening.

THERE has recently been launched in France a novel kind of vessel, named the *Ernest Bazin*, after the name of the inventor. This vessel, which is only a large model, is intended to demonstrate the feasibility of driving steamers through the water at high speeds without increasing the engine power, and consequently the quantity of coal required beyond practical mercantile limits. The inventor considers that it is possible, with vessels designed on his principle, measuring between 400 and 500 feet in length, to realise, with a consumption of 800 tons of coal, a speed of thirty knots, which means that the voyage from this country to America could be accomplished in 100 hours. As a comparison with this, vessels of the type of the *Campania* use between 3000 and 4000 tons of coal to attain a speed of twenty-two knots, and if this speed were increased to thirty knots, there would be required for each voyage 70,000 tons. This result is to be attained by constructing the vessel on a series of large hollow wheels or rollers, which are to be made to revolve. In the model there are three rollers on each side, the vessel itself being carried on a framework resting on the axles of the rollers. The rolling motion of these wheels offers much less resistance in displacing the water than the propulsion of a fixed body through it. The rotation of the floating wheels has the effect of transforming fixed into moving elements, each point of which flies before the resistance of the water in proportion to the advance of the float, the resistance consequently becoming lessened. By experiments, M. Bazin has shown with small models that when a vessel, designed on his principle, is moved through the water with the rollers fixed, it will be brought up by an object of sufficient size floating on the water coming in contact with the rollers. Whereas, when the rollers are made to revolve, it will pass over the obstacle without loss of speed, the obstruction sinking in the water and returning to the surface after the roller has passed. The possibility of building a roller-ship has been practically demonstrated. It remains yet to be seen what the effect will be as to speed and other conditions.

IT is a popular idea that the seeds of many plants pass unharmed through the digestive canal of birds, and, being voided with the excrements, reach the ground in a peculiarly favourable condition for germination; and this is generally believed to be especially the case with the mistletoe, the seeds, in this case, being deposited on the branches of the tree on which the mistletoe is parasitic. In a paper contributed to the *Transactions* of the Linnean Society, Mr. F. W. Keeble shows that this is at all events not universally the case with the *Loranthaceæ*, especially with the Cingalese species of *Loranthus*. The species of this genus with tubular flowers which are natives of Ceylon are ornithophilous, the bird most effective in their pollination being a honey-bird, a species of *Nectarinia*. In the large-flowered species, the buds remain closed; but, when tapped, the corolla-lobes fly open with an explosion, and the pollen is scattered. The closing of the flower-buds appears to serve the purpose of protecting the pollen against rain, while the violent expulsion of the pollen aids in its carriage by the visiting birds, their beaks being frequently found to be covered with pollen after visiting the flowers. When the fruit is ripe, the bird eats the succulent portion only, wiping out the seeds with its beak on to a branch of the tree, to which they thus become attached by their viscid coating. If swallowed, the seeds are found to be digested and destroyed.

A VALUABLE memoir by Prof. Augusto Righi, entitled "Sulla propagazione dell' elettricitá nei gas attraversati dai raggi di Röntgen," has just been published by Signori Gamberini é Parmeggiani, Bologna. Practically all the experimental work which has advanced the knowledge of Röntgen rays is brought together and coordinated in the memoir, full references to the original papers being given in each case.

THE Cambridge University Press is about to issue a "Manual and Dictionary of the Phanerogams and Ferns," by Mr. J. C. Willis, Director of the Royal Botanic Gardens, Ceylon. The work is in two volumes, printed on thin paper, the second of which can be placed in the pocket as a handbook for ready reference in a botanic garden or museum. The first volume serves as an introduction to the second or dictionary part, and deals with the vegetable morphology, variation, and the principles of classification in a decidedly original manner. It considers plants largely from a biological standpoint, and attempts to indicate the effects of the environment on the organisms.

THE *Annales* of the French Meteorological Office for 1894 have recently been published. They consist of three large quarto volumes: (1) Memoirs, containing a discussion of tracks of thunderstorms, magnetic observations at various places, with a summary of the principal disturbances, and a comparison of the curves with those furnished by the registration of earth-currents, showing the relation which exists between these phenomena; a discussion of the observations made on the Eiffel Tower, &c. (2) Observations made at French stations and in their colonies. (3) Rainfall values: the number of these stations is 2039, which exceeds those given in any previous year.

CHEMICAL papers abound in the volume of *Proceedings* (vol. xxiii. new series, 1895-96) just issued by the American Academy of Arts and Sciences. We select for special mention the following subjects of contributions to the volume:—The composition of the Ohio and Canadian sulphur petroleums, by Charles F. Mabery; the chemical potential of the metals, by Wilder D. Bancroft. Among the conclusions are: (1) The potential difference between a metal and an electrolyte is not a function of the concentration of the salt solution, nor of the nature of the positive ion, except in certain special cases. (2) It is a function of the electrode, of the negative ion, and of the solvent; a revision of the atomic weight of zinc, by T. W. Richards and E. F. Rogers; (with O = 16 the atomic weight found is 65·404; with O = 15·96, the value is 65·240; and for O = 15·88, it is 64·912); thermo-electric interpolation formulæ, by Silas W. Holman; melting points of aluminium (660°), silver (970°), gold (1072°), copper (1095°), and platinum (1760°), by S. W. Holman, R. R. Lawrence, and L. Barr. The melting point of gold was assumed by the observers, and upon it the other values more or less depend. There are also papers on the thermal conductivity of mild steel, the outline of Cape Cod, and the embryology of the star-fish.

ALL chemists will welcome the appearance of a new instalment (part 2 of vol. ii.) of the "Lehrbuch du Organischen Chemie," by V. Meyer and P. Jacobson, which has just been issued. The new part deals with the aromatic phenols, quinones, aldelydes, ketones, and carboxylic acids. With the next part, the second volume, which deals with the chemistry of carbon rings, will be completed.

MR. CROOKES has been experimenting with a solution of ucium nitrate, and a larger quantity of precipitated oxalate, both supplied by M. P. Barrière, the patentee of the alleged new element, lucium. In the *Chemical News* he describes his experiments, and states that the results have convinced him that the claim of lucium to form one of the chemical elements is not justified. Chemical examination confirms the results obtained by spectrum observations, that lucium is nothing but impure yttrium.

IN the current number of the *Zeitschrift für Physikalische Chemie*, H. Euler gives the results of a series of measurements of the electrolytic dissociation of some organic acids at different temperatures. On warming a solution of benzoic acid the ionisation—*i.e.* the fraction existing in the form of ions—increases until 35° C. is reached, after which it decreases, showing that the heat evolved by the change of the undissociated molecule into the ionic condition is negative at temperatures lower than 35°, and positive at higher temperatures. *m*-Oxybenzoic acid also has a maximum ionisation between 25° and 30°. In general the ionisation either increases or decreases continuously as the temperature is raised. These results are of interest in view of the belief, which is not unfrequently met with, that the ionisation necessarily increases with rise of temperature.

THE additions to the Zoological Society's Gardens during the past week include a Leopard (*Felis pardus*, ♀) from Ceylon, presented by Surgeon-Major N. Manders; two Tigers (*Felis tigris*, ♂ ♂) from India, presented by Captain Alex. W. Thornycroft, Royal Scots Fusiliers; a Malabar Squirrel (*Sciurus maximus*) from India, presented by Mr. G. W. Vidal; a Ring-tailed Coati (*Nasua rufa*), a —— Courlau (*Aramus*, sp. inc.), a King Vulture (*Gypagus papa*), three Violaceous Night Herons (*Nycticorax violaceus*) from South America, an Impeyan Monaul (*Lophophorus impeyanus*) from the Himalaya Mountains, purchased.

OUR ASTRONOMICAL COLUMN.

EPHEMERIS FOR COMET PERRINE.—The following positions for Perrine's comet have been computed by Otto Knopf, and are given in *Edinburgh Circular*, No. 51:—

Ephemeris for Berlin Midnight.

1896.	R.A. h. m. s.	Decl. ° ′	Brightness.
Dec. 4 ...	19 52 8 ...	+4 42·7 ...	0·99
5 ...	19 51 49 ...	4 14·7	
6 ...	19 51 31 ...	3 47·2 ...	1·00
7 ...	19 51 14 ...	3 20·2	
8 ...	19 50 59 ...	2 53·6	
9 ...	19 50 44 ...	2 27·5	
10 ...	19 50 31 ...	2 1·8 ...	1·01
11 ...	19 50 19 ...	1 36·5	
12 ...	19 50 7 ...	1 11·6	
13 ...	19 49 57 ...	0 47·1	
14 ...	19 49 47 ...	+0 23·0 ...	1·04

The brightness of this comet on November 2 has been taken as unity.

"THE ASTROPHYSICAL JOURNAL."—Among the articles of this journal for the present month may be noted Mr. W. J. Humphrey's further study of the effect of wave-lengths of lines in the arc spectra of certain elements. In this investigation he has examined the lines of several other elements, the best out of one hundred and seventy-five negatives having been employed. The new facts thus gleaned have necessitated a modification of his previous statement concerning the connection between the atomic weights and the shift of the lines. Prof. J. Fényi communicates a statement with two diagrams of the positions of the prominences on the solar limb at the time of the recent eclipse on August 8. Mr. Alexander Roberts, commenting on the growing importance of the value of the light ratio, adds some notes on a method of determining this quantity. Mr. Wadsworth, in continuation of the series of articles that has been given on "The Modern Spectroscope," describes an ingenious fluid prism without solid walls, and its use in an objective spectroscope. The general idea of the arrangement may be summarised quite briefly. A Littrow spectroscope has its axis of rotation arranged horizontally. The collimating beam from the slit falls on a free horizontal surface of a liquid contained in a glass or metal cell, and is there refracted. A mirror, also movable about the same axis, is immersed in the liquid at such an angle that it receives

the refracted ray normally, and reflects it back again to the observing telescope. This form of liquid prism is well adapted "for use in an astronomical spectroscope of either the compound or the objective type in connection with a polar heliostat, . . . the heliostat is arranged to send the beam down the polar axis instead of up, as is usually done." The author suggests that the instrument must be mounted so as to be entirely free from any vibration. Prof. Rowland continues his valuable tables of solar spectrum, wave-lengths extending here from 3133 to 3259. Prof. B. Hasselberg's researches on the spectra of metals are translated from the original, the metals here dealt with being cobalt and nickel. The author points out the great difficulty of eliminating impurities, and states that the iron spectrum of Kaiser and Runge is to a large extent contaminated with foreign lines, which fact has led him to make iron comparisons from his own photographs. The number of lines having the same position in the spectra of cobalt and nickel is found to be very great. We may mention also that two excellent photographs, showing the erection of the polar axis and declination axis of the Yerkes telescope, together

Erecting the declination axis of the Yerkes 40-inch refractor.

with a general view of the Observatory, are also given in this number.

The accompanying illustration is a reduced reproduction of the second of these photographs, and it gives a good idea of the immense scale of the undertaking.

PLANETARY NOTES.—M. Flammarion reports in a telegram, dated November 21 from Juvisy, that the observations of Mars made there show the doubling of the canals Cyclops, Cerbere, Galaxias, Brontes, Orcus and Euphrates (*Astr. Nach.*, No. 3387).

Herr Leo Brenner has also been making some interesting observations on the planets Uranus and Mercury, which he has communicated to the same number. As regards the first of these bodies, he has with his 7-inch Reinfelder refractor observed on twelve evenings (April 28 to July 9), and made the same number of drawings. The spots on the disc are, as he says, the dimmest he has ever seen on a planet's disc, but nevertheless he has made a rough determination of the planet's time of rotation, the deduced value being about eight hours. The planet was also noticed as being flattened at the poles, thus corroborating previous observations.

The observations of Mercury, which are illustrated by twenty drawings, indicate a comparatively greater amount of detail than one would expect. The drawings show that the movements of the surface markings are really the result of rotation, the value of this latter being about thirty-three to thirty-five hours. Herr Brenner says with regard to the longer period suggested by Schiaparelli, that "so far, I am perfectly certain that a rotation of about three months is quite out of the question." The drawings, he further remarks, indicate on single days distinct forward motions of the spots, the different appearances of the planet's disc at various times, the undoubted polar spots, and, further, the circumstance that the markings seen by him do not always assume the same positions as those seen by Schiaparelli and recorded on his chart. There seems, however, to be evidence that in some cases the spots seen by both observers are permanent markings, as is shown by a comparison of these drawings with Schiaparelli's map of 1890. Herr Brenner has also examined Prof. Vogel's drawings of Mercury, which, he finds, prove the accuracy of his (Brenner's) observations, and suggest the impossibility of a slow rotation.

A COMPANION TO θ-SCORPII.—Dr. T. J. J. See, with the help of the Arizona atmosphere and the 24-inch Clark refractor of the Lowell Observatory, has been able to discover that θ-Scorpii is attended by a faint satellite of the 13th magnitude (*Astr. Nach.*, No. 3387). In contrast to the reddish light of the primary, the companion appears of a greenish hue, making the system resemble Antares. The position of θ for 1900 will be R.A. 17h. 30m. 8·1s., Decl. $= -42^\circ\ 54'\ 1{\cdot}5''$. The discovery was made when the star was less than 12° in altitude, which speaks well for the position of the observatory.

THE ANNIVERSARY MEETING OF THE ROYAL SOCIETY.

LAST Monday was St. Andrew's Day, and, in accordance with the usual custom, the Anniversary Meeting of the Royal Society was held in the apartments of the Society at Burlington House. The auditors of the Treasurer's accounts having read their report, and the Secretary having read the list of Fellows elected and deceased since the last Anniversary, the President (Sir Joseph Lister) delivered the following address:—

Nineteen Fellows and four Foreign Members have been taken from the Royal Society by death since the last Anniversary Meeting.

The deceased Fellows are:—

John Russell Hind, December 23, 1895, aged 73.

The Right Hon. Hugh Culling Eardley Childers, January 29, 1896, aged 69.

General James Thomas Walker, February 16, 1896, aged 69.

Charles Chambers, March, 1896, aged 61.

William Sharp, April 10, 1896, aged 91.

Sir John Russell Reynolds, May 29, 1896, aged 68.

Sir George Johnson, June 3, 1896, aged 78.

Sir Joseph Prestwich, June 23, 1896, aged 84.

The Right Hon. Sir William Robert Grove, August 2, 1896, aged 85.

Alexander Henry Green, August 19, 1896, aged 64.

The Hon. Sir George Frederic Verdon, September 13, 1896, aged 62.

Sir John Eric Erichsen, September 23, 1896, aged 78.

Sir George Murray Humphry, September 24, 1896, aged 76.

Baron Ferdinand von Mueller, October 9, 1896, aged 71.

Henry Trimen, October 18, 1896, aged 53.

George Harley, October 27, 1896, aged 67.

Henry Newell Martin, October 28, 1896, aged 44.

Admiral Sir George Henry Richards, November 14, 1896, aged 76.

Sir Benjamin Ward Richardson, November 21, 1896, aged 68.

The Foreign Members are:—

Gabriel Auguste Daubrée, May 29, 1896, aged 82.

August Kekulé, July 13, 1896, aged 66.

Hubert Anson Newton, August 12, 1896, aged 66.

Hippolyte Louis Fizeau, September 18, 1896, aged 77.

Benjamin A. Gould, November, 1896.

Although biographical notices of all will be found in the *Proceedings*, there are some to whose labours I may make brief reference to-day.

Sir William Grove presented the rare spectacle of steady and distinguished devotion to science in spite of the claims of an exacting profession. Grove was an eminent lawyer. Called to the bar in 1835, he was for some time kept from active work by ill-health; but he subsequently acquired a considerable practice, and becoming a Queen's Counsel in 1853, was for some years the leader of the South Wales Circuit. His practice was mainly in patent cases, and the reputation he obtained in that field led to his being appointed a member of the Royal Commission on the Patent Laws. His work as an advocate was, however, by no means confined to such matters: he was one of the counsel—Sergeant Shee and Dr. Kenealy being the others—who defended the Rugeley poisoner, William Palmer, and he was engaged in many other *causes célèbres*.

The eminent position to which he had risen at the bar led to his appointment in November 1871, as a Judge of the old Court of Common Pleas, a post which in 1875 was converted by the Judicature Act into that of a Judge of the High Court. This office he held until his retirement in 1887, when he became a member of the Privy Council.

Throughout the greater part of his long and distinguished legal career, Grove's love of science impelled him to devote a large share of his energies to its pursuit. It is remarkable that his first paper, which was communicated to the British Association in 1839, and which also appeared in the *Comptes rendus*, and in Poggendorff's *Annalen*, contained a description of the "Grove's cell," which was afterwards used in every physical laboratory in the world. This was succeeded by a long series of memoirs, chiefly on electrical subjects, among which one of the best known is that on the gas battery. In 1842 he delivered, at the London Institution, an address which was, in the following year, developed into the celebrated series of lectures: "On the Correlation of Physical Forces." In these he discussed what we should now call the transformations of energy, and, though Prof. Tait, in his "Historical Sketch of the Science of Energy" ("Thermodynamics," p. 58), assigns precedence in calling "attention to the generality of such transformations" to Mrs. Somerville, there can be no doubt that Grove was an independent and very advanced thinker on that subject.

For many years Sir William Grove took a very prominent part in the affairs of the Royal Society, and was one of the most active promoters of the reform of its constitution, which took place in 1847. It is largely to his efforts that we owe our present system of electing only a specified number of Fellows in each year. He was also one of the founders of the "Philosophical Club," and was the last survivor of the original members.

He was President of the British Association in 1866, and, in the course of his address, observed: "The Kew Observatory, the petted child of the British Association, may possibly become an important national establishment; and, if so, while it will not, I trust, lose its character of a home of untrammelled physical research, it will have superadded some of the functions of the Meteorological Department of the Board of Trade, with a staff of skilful and experienced observers" ("Correlation and Continuity." Fifth Edition, 1867, p. 278). Although the British Association long ago handed over the care of its "petted child" to a Committee appointed by the Royal Society, the Society and the Association have lately appointed a joint Committee to urge the Government to supply the funds for converting the Kew Observatory into a "national establishment" similar to the Reichsanstalt at Charlottenburg. We are thus striving to realise to-day the suggestion thrown out, thirty years ago, by Grove.

In Sir Joseph Prestwich we have lost almost the last link that remained which connected geologists of the present day with the founders of the science in the first half of this century. To him we are indebted, not only for the first comprehensive classification of the tertiary beds of this country—to several of which he assigned the names by which they will henceforth be universally known—but, also, for their correlation with the strata of the Paris Basin. To him, also, is due the credit of having been the first to establish the authenticity of the remains of human workmanship found in the drift-deposits of the valley of the Somme, and of thus having laid secure foundations on which arguments as to the extreme antiquity of man upon the earth may be based. In France his name was known and respected as much as in England, and it would be hard to say how much of the advance in geological knowledge during the last sixty years was not due to his unintermitted labours, which extended over the whole of that period.

The earliest scientific investigation of Armand Hippolyte Louis Fizeau was on the use of bromine in photography, and was published in 1841. He will always be remembered as the first who carried out experiments designed to measure the velocity of light produced by a terrestrial source, and travelling through a comparatively small distance near the surface of the earth. These observations, made in 1849, were very difficult, but the velocity deduced from them differs by only about 5 per cent. from the mean of all the best modern results. The value of the method employed is attested by the fact that a quarter of a century afterwards it was adopted by M. Cornu, and that with the improved apparatus employed by him it gave results of the highest accuracy.

A few years afterwards Fizeau performed another classical experiment, by which he measured the change in the velocity of light produced by the motion of the medium in which it travels.

He also devised an extremely delicate method (based on the interference of light) of determining the coefficients of thermal expansion of small bodies, such as crystals. The instrument he designed has been carefully studied by the Bureau International des Poids et des Mesures, with very satisfactory results.

On account of these and other researches, M. Fizeau has, for nearly half a century, occupied a conspicuous position among European physicists. He was awarded the Rumford Medal in 1866, and became a Foreign Member of the Royal Society in 1875.

Our distinguished Foreign Member, Prof. Hubert Anson Newton, Senior Professor of Mathematics at the Yale University, New Haven, died at his home in New Haven on August 12 last. He was born at Sherbourne, in the State of New York, in 1830; studied at Yale College, where he graduated in 1850, and was called to the Chair of Mathematics in the University at the early age of twenty-five.

On the organisation of the Observatory of the University in 1882, Prof. Newton was appointed Director; but though he resigned this position in 1884, the whole policy and success of the Observatory ever since, and, indeed, its very existence, are in no small measure due to his warm interest and untiring efforts.

Prof. Newton's name will ever remain associated with his important researches on Meteor Astronomy, beginning as early as 1860; and with his inquiry into the possible capture of comets by Jupiter and other planets. His historical investigations, and discussions of the original accounts, showed that the phenomena of meteor showers are of a permanent character, and come within the range of Celestial Dynamics, and that predictions of returning meteoric displays are possible.

Prof. Newton was President of the American Association for the Advancement of Science in 1885, and was for many years an Associate Editor of the *American Journal of Science*. He was a man of noble character, held in universal esteem, and greatly beloved by all those to whom he was personally known.

The death of August Kekulé will be felt as a severe loss to chemical science all over the world. Not only did his great activity in original research enrich organic chemistry with many new and interesting compounds, but his announcement of the tetradic valency of carbon, and, especially, his theoretical conception of the benzene ring, gave an impulse to the study of structural chemistry which has introduced order into the vast array of organic compounds, both of the alcoholic and aromatic types, and has not, even yet, expended itself. In recognition of his lifelong work, the Council of the Royal Society awarded Prof. Kekulé the Copley Medal in 1885.

Another Foreign Member who has passed away from us during the year is the distinguished mineralogist and geologist, M. Daubrée. After leaving the École Polytechnique in 1832, he was sent on a mission to investigate the modes of occurrence of tin-ore in Cornwall and on the continent. His reports showed such ability that he was appointed Professor of Mineralogy and Geology at Strasburg, at the age of twenty-five; afterwards (1861–2) he became Professor of Geology at the Musée d'Histoire Naturelle at Paris, and at the same time Professor of Mineralogy at the École des Mines; in the same year he succeeded to the Chair at the Institut vacated by M. Cordier. From 1872 to 1884, when the rules of the Service made retirement by reason of age compulsory, he acted as Director of the École des Mines.

M. Daubrée was the leader in France in experiments for the synthetic reproduction of minerals and rocks, and his laboratory furnace was the first to yield crystals of oxide of tin having the lustre, colour, and hardness of the mineral cassiterite; his memoir on the zeolites and other minerals, produced since Roman times through the action of the hot springs of Plombières on the bricks and concrete, has been of general interest both to mineralogists and geologists. Other important experiments led him to infer that circulating water, rather than heat or vapours, has been the essential agent in all phenomena of rock transformation. M. Daubrée gave much attention to the description and classification of meteorites, and made numerous experiments relative to the reproduction of material having similar characters.

The Council was much occupied during the earlier part of the session with the consideration of the proposed "Standing Orders" relating to the conduct of the meetings, and to the publications of the Society—a subject which has engaged the anxious attention of previous Councils. In framing these Standing Orders two principal objects were kept in view. Firstly, to increase the interest of the meetings by giving greater freedom in the conduct of them, and by enlarging the opportunities for discussion; and secondly, to obtain a more secure, and, at the same time, more rapid judgment as to the value of communications made to the Society; so that, while the high standard of the *Philosophical Transactions* is retained, or even raised, greater rapidity in the publication of these and of the *Proceedings* may be attained. To secure these latter objects, the Council has called to its aid, in the form of Sectional Committees, a number of Fellows much greater than that of the Council itself, to whom will be entrusted the task of reviewing the communications to the Society, and of making to the Council such recommendations with respect to them as may seem desirable. It is further probable that by using the special knowledge of the several Sectional Committees in the detailed consideration of special questions, the Council will have more time at its disposal than it has at present to consider the matters of larger policy which are so frequently brought before it.

It soon became evident that no satisfactory Standing Orders securing these advantages could be drawn up which would not be in some way or other inconsistent with the Statutes at present in operation. It was accordingly resolved to modify the Statutes; and this has been done by giving to certain Statutes a more general form than that in which they have for a long time appeared, so that such alterations of detail as may from time to time seem desirable may be effected by changes in the Standing Orders only, without interfering with the Statutes. I gladly avail myself of this opportunity of acknowledging the great help which the Council received from Mr. A. B. Kempe, in respect to the many legal points which arose in connection with the change of Statutes. A copy of the Statutes, as amended during the present session, as well as of the Standing Orders adopted, will be found in the Year-book, which has been instituted by one of the new Standing Orders, and which will be published each year, as soon after the Anniversary Meeting as possible.

The International Conference called to consider the desirability and possibility of compiling and publishing, by international co-operation, a complete catalogue of scientific literature, was duly held; and the Society may be congratulated on the successful issue of a meeting, to the preparations for which a special International Catalogue Committee, appointed by, and acting under the authority of, the Council, had devoted much time and labour. The Conference met in the apartments of the Society on July 14, 15, 16, and 17, under the presidency of the Right Hon. Sir J. Gorst, Vice-President of the Committee of Council on Education, and was attended by forty-one delegates, representing nearly all countries interested in science. The Society was represented by the Senior Secretary, Prof. Armstrong (Chairman of the International Catalogue Committee), Mr. Norman Lockyer, Dr. L. Mond, and Prof. Rücker. Three other Fellows of the Society—Dr. D. Gill, Prof. Liversidge, and Mr. R. Trimen—were among the delegates appointed by Colonial Governments.

The Conference resolved that it was desirable to compile and publish a catalogue of the nature suggested in the original circular issued by the Royal Society, the administration being carried out by an International Central Bureau, under the direction of an International Council, with an arrangement that each of such countries as were willing to do so, should, by some national organisation, collect and prepare for the Central Bureau all the entries belonging to the scientific literature of the country. It was further resolved that the language of the catalogue should be English, and a proposal that the Central Bureau should be placed in London was carried by acclamation. The Conference finding itself unable to accept any of the systems of classification proposed, requested the Royal Society to form a Committee which should consider this and other matters which were left undecided by the Conference. The Council are already taking steps to perform the duties thus entrusted to them by the Conference.

The delegates of the Society reported that the whole proceedings of the Conference were carried on with remarkable good feeling, and even unanimity, and that the confidence felt and expressed by the various delegates in the fitness of the Royal Society to complete the work begun by the Conference was most gratifying.

In connection with the fact that the proposed International Catalogue is to be in part arranged according to subject matter, it may be stated that the Council, acting upon a resolution of the International Catalogue Committee, have taken steps towards the practice of appending subject indices to the papers published by the Society, and have recommended the same practice to other Societies.

The work connected with the Society's own Catalogue is progressing. Vol. XI, the last of the decade 1874–83, has been published, and the preparation of the Supplement, which has been found necessary for this and preceding decades, is being pushed on.

For the Subject Index to the Catalogue, slips have been prepared, and the Catalogue Committee will soon have to advise the Council as to the system of classification to be adopted.

The Grant of 1000*l.*, in aid of publications, which My Lords of the Treasury promised last summer to place upon the Estimates of this year, has been sanctioned by Parliament, and a moiety of it has already been paid to the Society. The Council have already felt the great advantage of having this money at their disposal, and have framed regulations for its administration, which they trust will be found to work satisfactorily.

The Council have made some small changes (which have been approved by My Lords of the Treasury) in the Regulations for the administration of the Government Grant of 4000*l.* in aid of scientific inquiries, directed chiefly towards more effectually securing that Grants made should be expended for the purpose for which they were given, and that objects of permanent interest obtained by Grants should be properly disposed of. The only two Grants made this year which call for special mention are that of 1000*l.* to the Joint Permanent Eclipse Committee of the Royal and Royal Astronomical Societies, for observations of the Solar Eclipse of August, and that of 800*l.* for boring a coral reef in the Pacific Ocean, administered by the Committee appointed by the Royal Society, both drawn from the Reserve Fund.

The Expedition to bore the Coral Reef received valuable assistance from My Lords of the Admiralty, who directed H.M.S. *Penguin* to carry the observers from Sydney, N.S.W., to Funafuti, the seat of the boring, and to render the Expedition all possible help during the whole of the operations. I desire to express on behalf of the Society our recognition of this renewed token of the willingness of My Lords of the Admiralty to further scientific inquiry. Though the full Report of the Expedition has not yet reached the Council, information has been received to the effect that the boring operations had to be suspended when a depth of only 75 feet had been reached; a layer of sand and boulders presenting obstacles which the experts employed were unable to overcome. It is much to be regretted that an undertaking which promised scientific results of very great value has thus so far failed.

The appeals of the Council to H.M. Minister for Foreign Affairs and to My Lords of the Admiralty for assistance to the Eclipse Expeditions met with most cordial and effective response, for which we would express our gratitude. We also desire to acknowledge the courtesy shown and help afforded to the observing parties in Norway and Japan by the respective Governments of those countries, and to record our high appreciation of the enthusiastic and effective aid given to those under the direction of Mr. Norman Lockyer, at Vadsö, by Captain King Hall and the officers and crew of H.M.S. *Volage*.

Both in Norway and in Japan unfavourable weather rendered to a large extent nugatory the elaborate preparations which had been made for observing the eclipse. But British astronomy was splendidly saved from failure on this important occasion by

the munificence and public spirit of Sir George Baden Powell, who fitted up, at his own expense, and accompanied an expedition in his yacht *Otario* to Novaya Zemlya. The instruments employed were provided by our Fellows, Mr. Lockyer, and Mr. Stone, of the Radcliffe Observatory, Oxford; and the observations were entrusted to Mr. Shackleton, one of the computers employed by the Solar Physics Committee. In brilliant weather photographic observations were made, which promise to yield novel results of a highly important character.

At the request of the President of the Board of Trade the Council nominated, in March, Profs. Kennedy and Roberts-Austen as two members of a Committee to investigate the loss of strength in steel rails. So far as I am aware, the Committee has not yet made its report. More recently, in July, the Council, at the request of H.M. Secretary for Colonial Affairs, appointed a Committee to consider, and if necessary to investigate, in conjunction with Surgeon-Major Bruce, who has made important researches in the matter, the disease caused in cattle in Africa by the Tsetse fly. The Committee is still engaged on the inquiry.

We believe that the Council, in cordially responding to requests like the above, and in freely placing at the disposal of H.M. Government its scientific knowledge and its acquaintance with scientific men, is performing one of its most important functions. The Council of the Royal Society is again and again called upon to approach H.M. Government on behalf of the interests of science, and when it does so always meets with a cordial reception and a respectful hearing, even on occasions when public necessities prevent a favourable reply being given to its requests. In return, the Council believes it to be its duty (when called upon to do so), not only to place its own time and labour ungrudgingly at the service of H.M. Government, but also to ask for the co-operation of other Fellows of the Society, or even other scientific men not Fellows of the Society, feeling confident that whenever the matter in hand has practical bearings beyond the simple advancement of Natural Knowledge, the value of a scientific man's time and energy will be duly considered.

Some correspondence has taken place with the War Office relative to resuming the borings in the Delta of the Nile, which were carried on for a time some years ago, and which, though not completed, yielded valuable results. The Expedition to the Soudan has, however, prevented anything being done. The Council learn with pleasure that the old borings, undertaken for a purely scientific object, have indirectly been a valuable means of supplying certain districts of the Delta with sweet water.

If anything had been needed to justify the meetings for discussion recently established, it would have been supplied by the brilliant success of that held during the present session on Colour Photography. On that occasion, M. Lippmann gave us a demonstration of results of unprecedented beauty, obtained by extremely simple means, though based on profound mathematical reasoning. Such meetings can only prove fruitful when they are held in consequence of some theme needing such a discussion as is afforded by a special meeting; and their occurrence must therefore be uncertain and irregular. The purpose for which they were instituted would be frustrated if they were held at times fixed in any formal way, irrespective of whether they were needed or not.

Three of the informal gatherings recently instituted, limited to Fellows of the Society, have been held during the session, and were judged to be very successful.

The Council has had occasion during the past session to present an address of condolence to her Majesty, the Patron of the Society, on the lamented death of Prince Henry of Battenberg, and to the Royal Academy on the occasion of the death of their President, Lord Leighton. In the absence of Council, during the recess, I sent another message of sympathy on the death of Sir J. Millais.

I had the privilege of presenting, on behalf of the Council, an address of congratulation to our late President, Lord Kelvin, on the occasion of his Jubilee, nobly celebrated in Glasgow last summer, by a very remarkable concourse of scientific men from all parts of the world, assembled to do him honour.

Addresses were also sent to our Foreign Member, Prof. Cannizzaro, on the celebration of his seventieth birthday, and to the University of Princeton, New Jersey, U.S.A., on the occasion of its Sesquicentenary Anniversary.

Under the guidance of the Scientific Relief Committee, the Council has during the year granted 100*l.* to assist scientific persons or their relatives in distress. The Council desire to call the attention of the Fellows to the fact that, during the year, as during past years, the income of the fund has exceeded its expenditure, and that more aid could be given than has been given. With the view of increasing the usefulness of the fund, the Council has added to the list of those who can make representations to the Council concerning relief the Presidents of the Mathematical, Physical, and Entomological Societies.

I cannot but give expression to my deep regret, shared, I am sure, by every Fellow, that Lord Rayleigh, whose tenure of office as Secretary has been marked as much by faithful devotion to the interests of the Society as by scientific brilliancy, has thought it right, in consequence of increasing pressure of other engagements, to retire. But I rejoice that the Council can submit to your suffrages a man well qualified to wear the mantle laid down by Lord Rayleigh.

The Fellows will be pleased to learn that Mr. Rix, who was compelled, by the condition of his health a year ago, to resign the position which he had held for many years with such great advantage to the Society, has much improved under the lighter labour of the Clerkship to the Government Grant Committee.

As his successor in the office of Assistant-Secretary, the Council, out of eighty-four candidates, unanimously selected Mr. Robert Harrison, who entered upon his duties on April 24 last.

The scientific work of the Society during the past year has been full of deep and varied interest. Early in the session the announcement of Röntgen's great discovery burst upon the world. Its wonderful applications to medicine and surgery attracted universal attention to it; and physicists everywhere have since been engaged in investigating the nature of the new rays. Perhaps no outcome of such inquiries has been more remarkable than the fact observed by our Fellow, Prof. J. J. Thomson, that the rays have the power of discharging electricity, both positive and negative, from a body surrounded by a non-conductor; a mass of paraffin wax, for example, behaving in their path for the time being like a conductor of electricity.

It appears that Lenard had before observed the discharge of both kinds of electricity through air by the rays with which he worked. Lenard's rays, however, differ from Röntgen's in being deflectable by a magnet, implying, in the opinion of most British physicists, that they are emanations of highly electrified particles of ponderable matter, while Röntgen's are regarded as vibrations in the ether. The question naturally arises whether Lenard, in the observations referred to, may not have been working with a mixture of Röntgen's rays and his own. While points like these are still under discussion by experts, we cannot but feel that the letter X, the symbol of an unknown quantity, employed originally by Röntgen to designate his rays, is still not inappropriate.

I have before referred to Lippmann's beautiful demonstration and discussion of colour photography in one of our meetings.

Very important researches have been made both by Lord Rayleigh and by Prof. Ramsay into the physical properties of the new substance, helium, discovered by Ramsay in the previous session. Among their most striking results is the fact ascertained by Rayleigh that the refractivity of helium is very much less than any previously known, being only 0·146; between three and four times less than that of hydrogen, the lowest that had before been observed, although helium has more than twice the density of hydrogen. And equally surprising is Ramsay's observation of the extraordinary distance through which electric sparks will strike through helium, viz., 250 or 300 mm. at atmospheric pressure, as compared with 23 mm. for oxygen and 39 for hydrogen. Such properties appear to indicate that in helium we have to do with an exceedingly remarkable substance.

The density of helium appears to be really slightly different according to the mineral source from which it is obtained; and this circumstance seems to give countenance to the opinion arrived at by Lockyer and also by Runge and Paschen, from spectroscopic investigation, that helium is not a perfectly pure gas. But whatever other gas or gases may be mixed with it, they must be as inert chemically as the main constituent; for all Ramsay's elaborate attempts to induce it, or any part of it, to combine with other bodies have entirely failed.

Prof. Roberts-Austen, in the Bakerian lecture, brought before us astonishing evidence that metals are capable of diffusing into each other, not only when one of them is in the state of fusion, but when both are solid. We learned that if clean surfaces

of lead and gold are held together *in vacuo* at a temperature of only 40° for four days, they will unite firmly and can only be separated by a force equal to one-third of the breaking strain of lead itself. And gold placed at the bottom of a cylinder of lead 70 mm. long thus united with it, will have diffused to the top in notable quantities at the end of three days. Such facts tend to modify our views concerning the mutual relations of the liquid and solid states of matter.

Such are a few samples of the many highly interesting communications we have had in physics and chemistry. On the biological side, also, there has been no lack of important work. Of this I may refer to one or two instances.

Prof. Schäfer has given us an account of the well-devised experiments by which he has conclusively established that the spleen is on the one hand capable, like the heart, of independent rhythmical contractions, and, on the other hand, has those contractions controlled by the central nervous system acting through an extraordinary number of efferent channels.

Prof. Farmer and Mr. Lloyd-Williams made a very beautiful contribution to biology in the account they gave of their elaborate investigations on the fertilisation and segmentation of the spore in Fucus. Especial interest attached to this communication, from the fact that it described in a vegetable form exactly what had been established by Oscar Hertwig in Echinodermata, viz., that out of the multitude of fertilising elements that surround the female cell, one only enters it and becomes blended with its nucleus.

Lastly, I may mention the very remarkable investigation into the development of the common eel, which was described to us a fortnight ago by Prof. Grassi, to which I shall have occasion to refer in some detail when speaking of his claims to one of the Society's medals.

These, as I have before said, are but samples of what we have had before us; but I think they are in themselves sufficient to justify the statement that in point of scientific interest the past year has been in no degree inferior to its predecessors.

COPLEY MEDAL.

Prof. Carl Gegenbaur, For. Mem. R.S.

The Copley Medal for 1896 is given to Carl Gegenbaur, Professor of Anatomy in Heidelberg, in recognition of his pre-eminence in the science of Comparative Anatomy or Animal Morphology. Professor Gegenbaur was born in 1826, and a few weeks ago his seventieth birthday was celebrated by his pupils (who comprise almost all the leading comparative anatomists of Germany, Holland, and Scandinavia) by the presentation to him of a "Festschrift" in three volumes. Gegenbaur is everywhere recognised as the anatomist who has laid the foundations of modern comparative anatomy on the lines of the theory of descent, and has to a very large extent raised the building by his own work. His "Grundzüge der vergleichenden Anatomie" was first published in 1859, when he was thirty-three years old. In the second edition, published in 1870, he remodelled the whole work, making the theory of descent the guiding principle of his treatment of the subject. Since then he has produced a somewhat condensed edition of the same work under the title of "Grundriss" (translated into English and French), and now, in his seventy-first year, he is about to publish what will probably be the last edition of this masterly treatise, revising the whole mass of facts and speculations accumulated through his own unceasing industry and the researches of his numerous pupils during the past quarter of a century.

Gegenbaur may be considered as occupying a position in morphology parallel to that occupied by Ludwig in Physiology. Both were pupils of Johannes Müller, and have provided Europe with a body of teachers and investigators, carrying forward in a third generation the methods and aims of the great Berlin professor. Gegenbaur's first independent contribution to science was published in 1853. It was the outcome of a sojourn at Messina in 1852, in company with two other pupils of Johannes Müller, namely Albert Kolliker (still professor in Würzburg) and Heinrich Müller, who died not long afterwards. These young morphologists published the results of their researches in common. Gegenbaur wrote on Medusæ, on the development of Echinoderms, and on Pteropod larvæ. A long list of papers on the structure and development of Hydrozoa, Mollusca, and various invertebrata followed this first publication. The greatest interest, however, was excited among anatomists by his researches on the vertebrate skeleton (commenced already in 1849 with a research, in common with Friedreich, on the skull of axolotl). In a series of beautifully illustrated memoirs he dealt with and added immensely to our knowledge of the vertebral column, the skull, and the limb-girdles and limbs of Vertebrata, basing his theoretical views as to the gradual evolution of these structures in the ascending series of vertebrate forms upon the study of the cartilaginous skeleton of Elasmobranch fishes, and on the embryological characters of the cartilaginous skeleton and its gradual replacement by bone in higher forms. His method and point of view were essentially similar to those of Huxley, who independently and contemporaneously was engaged on the same line of work.

For many years Gegenbaur was professor in Jena, where he was the close friend and associate of Ernst Haeckel, but in 1875 he accepted the invitation to the chair of Anatomy in Heidelberg, and in view of the increased importance of his duties as a teacher of medical students, and therefore of human anatomy, though still continuing his researches on vertebrate morphology, he produced a large treatise on that subject, which has run through two editions. In this work he made the first attempt to bring, as far as possible, the nomenclature and treatment of human anatomy into thorough agreement with that of comparative anatomy, and to a very large extent the changes introduced by him have influenced the teaching of human anatomy throughout Europe and America.

There is probably no comparative anatomist or embryologist in any responsible position at the present day who would not agree in assigning to Gegenbaur the very first place in his science as the greatest master and teacher who is still living amongst us. He is not only watching in his old age the developments of his own early teaching and the successful labours of his very numerous disciples, but is still exhibiting his own extraordinary industry in research, his keenness of intellectual vision, and his unrivalled knowledge and critical judgment.

ROYAL MEDAL.

Sir Archibald Geikie, F.R.S.

One of the Royal Medals is conferred on Sir Archibald Geikie, on the ground that of all British geologists he is the most distinguished, not only as regards the number and the importance of the geological papers which he has published as an original investigator, but as one whose educational works on geology have had a most material influence upon the advancement of scientific knowledge.

His original papers range over many of the main branches of geological science. His memoir upon the "Glacial Drift of Scotland" (1863) is one of the classics in British geology. His work on the "Scenery of Scotland, viewed in connection with the Physical Geology" (1865) was the first successful attempt made to explain the scenery of that country upon scientific principles, and is still without a rival. His papers on the "Old Red Sandstone of Western Europe" (1878—79) gave for the first time a clear and convincing picture of the great lake period of British geology, founded upon personal observation in the field.

His many original contributions to the volcanic history of the British Isles form a succession of connected papers, crowded with important observations and discoveries, and brilliant and fertile generalisations respecting the abundant relics of former volcanic activity in the British Isles from the earliest geological ages to Middle Tertiary times.

In the first series of these papers—commencing with the "Chronology of the Trap Rocks of Scotland" (1861), and ending with the "Tertiary Volcanic Rocks of the British Isles" (1869), abundant original proofs were advanced of the activity of volcanic action in the Western Isles of Scotland, and of its long duration in geological time. The second series (1871–88) was especially distinguished by the publication of his remarkable paper on the "Carboniferous Volcanic Rocks in the Basin of the Firth of Forth," our earliest, and, as yet, our only monograph on a British volcanic area belonging to a pre-Tertiary geological system. The third series (begun in 1888) commenced with his memoir on the "History of Volcanic Action during the Tertiary Period in the British Isles," a paper which is by far the most detailed and masterly contribution yet made to the subject, and for which the Brisbane Medal was awarded him by the Royal Society of Edinburgh; and this succession of papers has been followed by the publication of others of almost equal importance.

Sir Archibald Geikie has also written many papers and memoirs bearing upon geological processes and their effects,

[Photographed by Lantin, Aachen.

PROF. PHILIPP LENARD (*Rumford Medallist*).

[Photographed by E. Hanfstaengl, Frankfurt a/M.

PROF. W. C. RÖNTGEN (*Rumford Medallist*).

[Photographed by Le Lieure, Rome.

PROF. G. B. GRASSI (*Darwin Medallist*).

[Photographed by Melhuish, 58 Pall Mall, S.W.

PROF. C. V. BOYS (*Royal Medallist.*)

which have become permanent parts of our scientific literature. While carrying out this highly important original work in Geology, Sir Archibald has most materially contributed to the advancement and diffusion of scientific knowledge by his many educational works upon Geology and Physical Geography. His "Elementary Lessons on Physical Geography" has passed through several English and foreign editions; his "Outlines of Field Geology" is now in its fifth edition; and his article on Geology—originally contributed to the "Encyclopædia Britannica" in 1879—was afterwards expanded by him into his well-known "Text-book of Geology," which has become the acknowledged British standard of Geology in general.

ROYAL MEDAL.

Prof. C. V. Boys.

The other Royal Medal is awarded to Prof. Boys, who has given to physical research a method of measuring minute forces far exceeding in exactness any hitherto used, by his invention of the mode of drawing quartz fibres, and by his discovery of their remarkable property of perfect elastic recovery.

Prof. Boys has himself made several very important researches in which he has employed these fibres to measure small forces. Using a combination of a thermo-junction with a suspended coil in a galvanometer of the usual D'Arsonval type, a combination first devised by D'Arsonval himself, Prof. Boys developed the idea in the microradiometer, an instrument rivalling the bolometer in the measurement of small amounts of radiation. Its sensitiveness and accuracy were obtained in part by the use of a quartz fibre to suspend the coil, in part by the admirable design of every portion of the instrument. Prof. Boys was the first to show its value in an investigation into the radiation received from the moon and stars.

In this great research on the value of the Newtonian constant of attraction, Prof. Boys used quartz fibres to measure the gravitation forces between small bodies by the Michell-Cavendish torsion method. He redesigned the whole of the apparatus, and, calculating what should be the dimensions and arrangements to give the best results, he was led to the remarkable conclusion that accuracy was to be gained by a very great reduction in the size of the apparatus. This conclusion he justified by a determination of the value of the Newtonian constant, which is now accepted as the standard.

Prof. Boys has also made some remarkable studies by a photographic method of the motion of projectiles, and of the air through which they pass.

All his work is characterised by the admirable adjustment of the different parts of the apparatus he uses to give the best results. His instruments, are, indeed, models of beauty of design.

RUMFORD MEDAL.

Prof. Philipp Lenard and Prof. W. C. Röntgen.

In the case of the Rumford Medal, the Council have adopted a course, for which there are precedents in the awards of the Davy Medal, but which is, as far as the Rumford Medal itself is concerned, a new departure. They have decided to award the Medal in duplicate. It has often happened in the history of science that the same discovery has been made almost simultaneously and quite independently by two observers, but the joint recipients of the Rumford Medal do not stand in this relation to each other. Each of them may fairly claim that his work has special merits and characteristics of its own. To-day, however, we have to deal not with points of difference, but with points of similarity. There can be no question that a great addition has recently been made to our knowledge of the phenomena which occur outside a highly exhausted tube through which an electrical discharge is passing

Many physicists have studied the luminous and other effects which take place within the tube; but the extension of the field of inquiry to the external space around it is novel and most important. There can be no doubt that this extension is chiefly due to two men—Prof. Lenard and Prof. Röntgen.

The discussion which took place at the recent meeting of the British Association at Liverpool proved that experts still differ as to the exact meaning and causes of the facts these gentlemen have discovered. No one, I believe, disputes the theoretical interest which attaches to the researches of both; or the practical benefits which the Röntgen rays may confer upon mankind as aids to medical and surgical diagnosis. But whatever the final verdict upon such points may be, the two investigators whom we honour to-day have been toilers in a common field, they have both reaped a rich harvest, and it is, therefore, fitting that the Royal Society should bestow upon both of them the Medal which testifies to its appreciation of their work.

DAVY MEDAL.

Prof. Henri Moissan.

The Davy medal is given to Prof. Henri Moissan.

Notwithstanding the abundant occurrence of fluorine in nature, the chemical history of this element and its compounds has until recently been scanty in the extreme, and, as far as the element in the free state is concerned, an entire blank. And yet from its peculiar position in the system of elements, the acquisition of a more extended knowledge of its chemical properties has always been a desideratum of the greatest scientific interest.

The frequent attempts which have been made from time to time to clear up its chemical history have been constantly baffled by the extraordinary difficulties with which the investigation of this element is beset.

Thanks to the arduous and continuous labours of M. Moissan, this void has been filled up. He has effected the isolation of fluorine in a state of purity, and prepared new and important compounds, the study of which has placed our knowledge of the chemical and physical properties of this element on a level with that of its immediate allies.

During the last few years M. Moissan has turned his attention to the study of chemical energy at extremely high temperatures, and by the aid of the electric furnace, which he has contrived, he has succeeded in obtaining a large number of substances whose very existence was hitherto undreamt of. It is impossible to set bounds to the new field of research which has thus been opened out. The electric furnace of M. Moissan has now become the most powerful synthetical and analytical engine in the laboratory of the chemist.

On studying the accounts which Moissan has given of his researches, we cannot fail to be struck with the originality, care, perseverance and fertility of resource with which they have been carried on. The Davy Medal is awarded to him in recognition of his great merits and achievements as an investigator.

DARWIN MEDAL.

Prof. Giovanni Battista Grassi.

The Darwin Medal for 1896 is awarded to Prof. Grassi, of Rome (late of Catania), for his researches on the constitution of the colonies of the Termites, or White Ants, and for his discoveries in regard to the normal development of the Congers, Murænæ, and Common Eels from Leptocephalus larvæ.

From a detailed examination of the nature and origin of the colonies of the two species of the Termites which occur in the neighbourhood of Catania, viz., *Termes lucifugus* and *Calotermes flavicollis*, he was able to determine certain important facts which have a fundamental value in the explanation of the origin of these and similar polymorphic colonies of insects, and are of first-rate significance in the consideration of the question of the share which heredity plays in the development of the remarkable instincts of "neuters," or arrested males and females, in these colonies. Prof. Grassi has, in fact, shown that the food which is administered by the members of a colony to the young larvæ determines, at more than one stage of their development, their transformation into kings or queens, or soldiers or workers as the case may be, and the value of these researches is increased by the observations which he has made on the instincts of the different forms, showing that they do not in early life differ from one another in this respect, and are all equally endowed with the potentiality of the same instincts. These do not, however, all become developed and cultivated in all alike, but become specialised, as does the physical structure in the full-grown forms.

A very different piece of work, but having a no less important bearing on the theory of organic evolution, is that on the Leptocephali. These strange, colourless, transparent, thin-bodied creatures, with blood destitute of red corpuscles, had been regarded as a special family of fishes, but have been proved by Grassi's patient and long-continued labours to be larval forms of the various Murænoids. The most astonishing case is that of the Common Eel (*Anguilla vulgaris*), the development of which had been a mystery since the days of Aristotle. It had been long known that large eels pass from rivers into the sea at certain seasons, and that diminutive young eels, called in this country Elvers, ascend the rivers in enormous numbers. But,

although the species is very widely distributed, no one in any country had been able to discover how the elvers were produced. Grassi has shown that, large as the eels are that pass into the sea, they are not perfectly developed fish, but only attain maturity in the depths of the ocean. There they in due time breed, and from their eggs are hatched the young Leptocephali, which, after attaining a certain size, cease to feed, and assume the very different form of the elver. The possibility of establishing these remarkable facts depended on the powerful oceanic currents that prevail about the Straits of Messina, bringing up occasionally to the surface the inhabitants of the depths of the sea. Grassi was thus able to obtain, from time to time, both adult eels with fully developed sexual organs and their larval progeny, and he actually observed in an aquarium the development of a *Leptocephalus brevirostris* into an elver.

Such highly meritorious contributions to evolution are fitly recognised by the award of the Darwin medal.

The Society next proceeded to elect the Officers and Council for the ensuing year. The list suggested by the President and Council, and adopted by the Society, was given in these columns on November 12 (p. 38).

[Photographed by Martin Jacobette, Queen's Gate Hall, South Kensington.

PROF. A. W. RÜCKER (*appointed Junior Secretary*).

[We are glad to be able to give portraits of the new Secretary of the Society, and of the recipients of the Rumford medal, Royal medal, and Darwin medal. It was unnecessary to include Sir Archibald Geikie's portrait among these, as it has already been given in our series of Scientific Worthies; and we regret that we have not received the portraits of Prof. Gegenbaur and M. Moissan.]

In the evening the Fellows and their friends dined together at the Whitehall Rooms, Hôtel Métropole, the attendance being larger than any up to the present time. Amongst the guests of the Society were the American Ambassador, the Italian Ambassador, the Speaker of the House of Commons, and the Lord Mayor.

After the usual loyal toasts had been drunk, the President proposed "The Legislature," and the Speaker of the House of Commons responded. The American Ambassador proposed "The Royal Society," and the toast was acknowledged by the President. M. Henri Moissan responded to the toast of "The Medallists." Sir John Lubbock proposed the health of the retiring Secretary (Lord Rayleigh) and the present Secretary (Prof. Rücker), both of whom responded, the evening concluding with the toast of "The Guests," proposed by Prof. Rücker, and acknowledged by the Lord Mayor.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Convocation has approved the holding of an examination in the theory, history and practice of education. The examination is to be held every year, and will be open to members of the University and others, subject to certain regulations. No member of the University is to be admitted who has not kept residence for at least seven terms. "The delegates of local examinations shall have power to make arrangements for lectures and courses of instruction to be given within the University on the theory, history and practice of education. They shall also have power to make arrangements with the managers or teachers of any secondary or other school, whereby students who purpose to be teachers in secondary schools may acquire a practical knowledge of educational methods."

Mr. C. W. M. Bromley, of Kendal Grammar School, has been elected to a Scholarship, and Mr. A. G. Gibson, of Aberystwyth College, to a College Exhibition in Natural Science at Christ Church.

The Junior Scientific Club held a meeting on Friday, November 27. Mr. E. S. Goodrich exhibited a cast of Heloderma and some specimens of a deep-sea Cephalopod. Papers were read by Mr. R. Wilkinson on the varieties of *Colias edusa* and *hyale* in England and Switzerland, and by Mr. E. F. Morris on dyeing.

The Provost of Oriel has been re-elected a Delegate of the University Museum.

Messrs. E. S. Craig (University College), J. A. Gardner (Magdalen College), M. S. Pembrey (Christ Church), and W. Garstang (Lincoln College) have been approved by Convocation as examiners for the preliminary examinations in the Honour School of Natural Science.

LORD REAY has been elected President of the University College, London, in succession to the late Sir John Erichsen.

UNDER the will of Mrs. Roxburgh, who died last week, the Bath Technical Schools are bequeathed one-fourth of the residuary estate, after legacies to certain charities have been deducted, to provide scholarships; while the remainder, about £8000, is to be used for the erection of an art gallery.

THE following appointments are announced: Dr. Karl Möbius, professor of zoology in Berlin University, to succeed Prof. Beyrich as director of the Natural History Museum there; Dr. W. Dames, professor of geology, to be director of the geological section of the same museum; Dr. Emil Schmidt to be professor of anthropology in Leipzig University; Dr. Ernst Pringsheim to be associate professor of physics at Berlin; Dr. Traube and Dr. Friedheim to be associate professors of chemistry at Berlin; Dr. Kepinski to be associate professor of mathematics at Krakau; M. Poincaré to be professor of mathematical astronomy and celestial mechanics in the University of Paris, and M. Boussinesq to be professor of mathematical physics in the same University; Prof. Schenk to be professor of anatomy in the University at Vienna; and Dr. London, of the University of Breslau, to be associate professor of mathematics there; Dr. Kippenberger, Privat-docent at Jena, to be professor of chemistry in the medical school at Kairo; Dr. R. H. Saltet to be professor of hygiene at Amsterdam, in succession to Dr. M. J. Foster; Dr. Gilson to be extraordinary professor of chemistry and pharmacy at Ghent; Dr. C. Julin to be professor of anatomy at Liège; Dr. Theodor Beer to be privat-docent in comparative anatomy at Vienna; Dr. Bubnoff, of Iurieff (Dorpat), to be professor of hygiene at Moscow, in succession to Prof. Erisman.

THE necessity of early legislation for the promotion of technical and secondary education was urged by a large and influential deputation, representing many educational bodies and associations, which waited upon the Duke of Devonshire on Wednesday in last week. In introducing the deputation, Sir Henry Roscoe

referred to the Report of the Royal Commission on Secondary Education, and the remarkable unanimity with which it had been received by educationists. (For a criticism of the Report from the scientific side, see NATURE, vol. liii. p. 79.) The bodies for which he spoke approached the subject especially from the point of scientific and technical education of the country. It is an acknowledged fact that the higher technical education of the country suffers from the lack of suitable preparation in the secondary schools, and that little can be hoped for in the way of systematic and advanced technical instruction until a basis of secondary education, such as has long existed in continental countries, has been established. Fortunately this organisation, for which Sir Henry Roscoe pleaded on behalf of the deputation, is unaccompanied by many of the difficulties which surround the subject of primary education, and, therefore, in this case Parliamentary unanimity in securing the great benefits which such a secondary system would confer upon the country might be expected. No detailed statement was made as to the form which legislation should take, but Sir Henry Roscoe pointed out that the most important recommendations of the Royal Commission are, in the first place, the establishment of local authorities, consisting of not smaller areas than counties and county boroughs, and, in the second place, of a central authority, chiefly of an advisory character. After several other members of the deputation had spoken, the Duke of Devonshire said that the Government hoped to deal with the better organisation of secondary schools in the next session of Parliament. It is intended to follow, generally speaking, the lines which were indicated in the proposed measure of last year.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, November 27.—Prof. Rücker, Vice-President, in the chair.—The President (Captain Abney) described and exhibited some apparatus for giving diagrams of the efficiency of a photographic shutter. In addition to the "speed" of a shutter, which is concerned with the interval (T) between the moments when the shutter admits the *first* and *last* rays of light, it is most important to know the efficiency of the shutter. The efficiency may be defined as follows: Let x represent the portion of the available aperture of the lens exposed by the shutter at a time t, and let X be the total available aperture. Then if the shutter were perfectly efficient, *i.e.* if the whole of the aperture were efficient during the time T, the quantity of light admitted would be proportional to XT. In other cases the quantity of light admitted will be proportional to $\int_0^T x dt$. Hence the efficiency is

$$\frac{\int_0^T x dt}{XT}.$$

The apparatus employed by the author consists of a slit placed near the shutter, so that the length of the slit is at right angles to the direction of motion of the shutter, and a lens by means of which an image of the slit is thrown on to a rotating drum or plate. The slit, when the shutter is open, is illuminated by the light of an arc lamp, a condensing lens being employed. In order to obtain a time scale two devices have been employed. In one of these a spoked wheel is rotated at a known speed so that each spoke, as it passes, momentarily cuts off the light. In the other arrangement a small lens, attached to the prong of a tuning-fork, throws a small spot of light on to the rotating drum, and thus gives a wavy line. Bromide paper or celloidin films are employed to record the diagrams. If the shutter were perfectly efficient, the diagram would consist of a rectangle crossed, if the rotating wheel is used, by a number of white lines, caused by the interruption of the light by the spokes of the wheel. These lines give a time scale by which the speed of the shutter can be calculated. The author showed a number of diagrams taken by the apparatus and illustrating the behaviour of different shutters under varying conditions. In one of these the rebound of the shutter at quick speeds is clearly shown by each of the principal diagrams being followed by a small auxiliary one. Prof. Perry said he supposed that what was required was some method of showing the *motion* of the shutter. Mr. Boys suggested that the efficiency might be defined as the ratio of the area of the actual diagram to that of the rectangle having as base the time between the commencement and end of the exposure. Mr. Inwards asked if the author had made any experiments to determine the amount of shake communicated to the camera by the motion of the shutter. Prof. Perry said what was required was an exceedingly light shutter that got up a great speed before it reached the aperture. The author, in his reply, said he had investigated the question of the shake due to the movement of the shutter. He considered that the amount of this shake depended upon the extent of the movement of the centre of gravity of the shutter. With a small stop the Thornton-Pickard shutter fulfilled Prof. Perry's requirements. The experiments have shown that the exposure does not always vary as the square of the aperture, on account of the small efficiency of some shutters for oblique rays. Thus in one case, by doubling the aperture, you only increase the light threefold.

Royal Meteorological Society, November, 18.—Mr. E. Mawley, President, in the chair.—Mr. W. Ellis, F.R.S., gave an account of the Proceedings of the recent International Meteorological Conference, which was held at Paris, from September 17 to 23. The Hon. F. A. Rollo Russell read a paper on haze, fog and visibility. Haze is most prevalent when the wind is from the north-east, and is due probably to excess of dust brought about by conflicting currents. The causes of fog are to a great extent the same as the causes of haze, although radiation in certain states of the air and ground plays a more conspicuous part. The main cause of fog is mixture of airs of different temperatures; and the attainment of a size of water particle so much larger than in the case of haze is due to suddenness of mixture, greater humidity, or greater differences of temperature. The conditions favourable to visibility are dryness of the air near the ground level, uniformity of temperature and moisture, radiation below the mean, steady and homogeneous winds through a great depth of the atmosphere, approximation of the temperatures of sea and land, and a number of dust particles less than the mean.

PARIS.

Academy of Sciences, November 23.—M. A. Cornu in the chair.—On some properties of uranic rays, by M. H. Becquerel. The rays emitted by uranium and its salts have some properties in common with the X-rays, but differ from them in being reflected and refracted like light. Even after eight months in complete obscurity, this radiation from uranium and its salts remains unchanged. The property of discharging an electrified body, which is communicated to a gas by exposure to the X-rays, or by transmitting electric sparks through it, is also possessed by air which has passed over uranium in the dark.—Decimalisation of the hour, by M. Bouquet de la Grye.—Theoretical study on the pitching of submarine vessels, by M. Leflaive. An investigation of the relations between the displacement, speed, and depth under water; the pitching is also studied, and the results displayed graphically.—On a particular case of the motion of liquids, by M. E. Fontaneau.—Euclid's postulate, considered as a property of three-dimension space, by M. G. Morosov.—Observations on the new Perrine Comet (1896, November 2) made at the Observatory of Algiers, by MM. Rambaud and Sy.—On algebraic curves of constant torsion, by M. Eugène Fabry.—On an application of the theory of continued groups to the study of the singular points of linear differential equations, by M. F. Marotte.—On the singularities of the equations of dynamics, and on the problem of three bodies, by M. P. Painlevé.—On the movement of a solid in an infinite liquid, by M. R. Liouville.—On the distribution of deformations in metals submitted to stresses, by M. George Charpy. A continuation of the discussion with M. Hartmann.—Discharges by the Röntgen rays; influence of temperature and pressure, by M. Jean Perrin. It is found that for the same gas, at a constant temperature the quantity of electricity lost per unit mass of gas is independent of the pressure, and proportional to the absolute temperature. It is noteworthy that according to the kinetic theory of gases the energy possessed by a molecule is also independent of the pressure and proportional to the absolute temperature.—Illusions which accompany the formation of penumbra, and applications of these to the X-rays, by M. G. Sagnac. No conclusions can be drawn from any peculiarities exhibited by shadows, without taking into account the extent and form of the source, the relative lustre of its different points, the form and position of the opaque body, and the photometric properties of the retina or photographic plate. The precaution should always be taken of replacing the Röntgen tube, in any

given experiment, by a luminous source emitting ordinary light, and of a shape and lustre as nearly similar as possible to the Crookes' tube.—Action of some hydrogen compounds upon thionyl chlorides, by M. A. Besson. With hydrogen iodide complete decomposition occurs, with formation of hydrogen chloride, iodine, sulphur dioxide, and sulphur. With hydrogen sulphide in a freezing mixture of ice and salt the main reaction is

$$2SOCl_2 + 2H_2S = 4HCl + SO_2 + 3S,$$

but a little S_2Cl_2 is formed in a secondary reaction, especially if the temperature is allowed to rise. Hydrogen phosphide gives hydrogen chloride, and a mixture of P_4S_3, phosphorus, $POCl_3$ and $PSCl_3$.—On the neutral crystallised chromite of magnesium, by Em. Dufau.—The salts of hexamethylene, by M. Marcel Delépine. Measurements of the heat of neutralisation by hydrochloric, sulphuric, nitric, and oxalic acids, and the heat of solution of the hydrochloride, the three sulphates, and two nitrates.—The function of boric acid in glasses and enamels, by M. L. Grenet. An experimental study of the relation between the quantity of boric acid in a glass and its coefficient of expansion.—On the non-retractile blood clot; suppression of the formation of blood serum in some pathological states, by M. G. Hayem.—Research on caramel in wines. Possible confusion with coal-tar colours, by M. A. J. da Cruz Magalhaës.—On the osmotic pressure in germinating grains, by M. L. Maquenne. The osmotic pressure was determined indirectly by taking the freezing points of the expressed juices. The values found in some cases approached ten atmospheres.—On the Elasipoda collected by the *Travailleur* and *Talisman*, by M. Rémy Perrier.—On compound nucleoles, especially in the egg of the Annelida, by M. Auguste Michel.—On the development of the "Black Rot" in the vine, by M. P. Viala.—On the development of a fungus in a liquid in motion, by M. Julien Ray.—Geological researches in the Central Caucasus, by M. Vénukoff.

DIARY OF SOCIETIES.

THURSDAY, DECEMBER 3.

LINNEAN SOCIETY, at 8.—Does Natural Selection play any part in the Origin of Species among Plants: Rev. Geo. Henslow.

CHEMICAL SOCIETY, at 8.—Election of Fellows.—Constitution and Colour: Arthur G. Green.—Some Experiments on Sea-water: E. Sonstadt.—Derivatives of α-Hydrindone: C. Revis and Dr. F. S. Kipping.—Notes on Nitration: Dr. H. E. Armstrong.—2: 3′ Bromobetanaphthol: Dr. H. E. Armstrong and W. A. Davis.—Derivatives of Nitrobetanaphthols: W. A. Davis.—Morphotropic Relations of Betanaphthol Derivatives: W. A. Davis.—Researches on Tertiary Benzenoid Amines: Miss C. Evans.

FRIDAY, DECEMBER 4.

GEOLOGISTS' ASSOCIATION, at 8.—The Foraminifera of the Thanet Beds of Pegwell Bay: H. W. Burrows and Richard Holland.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Address by J. Wolfe Barry, C.B., F.R.S. (President).—Railway Signalling: David W. Kinmont.

SUNDAY, DECEMBER 6.

SUNDAY LECTURE SOCIETY (St. George's Hall), at 4.—New Zealand—the World's Wonderland: W. Herbert-Jones.

MONDAY, DECEMBER 7.

SOCIETY OF ARTS, at 8.—The Use of Gas for Domestic Lighting: Prof. Vivian B. Lewes.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—A Journey to the Sources of the Niger: Colonel J. K. Trotter.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—The Alkali Manufacture: An Historical Sketch: Alfred E. Fletcher.—Notes on the Spontaneous Oxidation of Aluminium in contact with Mercury: H. F. Hunt and L. J. Steele.

VICTORIA INSTITUTE, at 4.30.

TUESDAY, DECEMBER 8.

ANTHROPOLOGICAL INSTITUTE, at 8.30.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Tipping and Screening Coal: James Rigg.—The Surface Plant at Kirkby Colliery: Thos. Gillott.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.—Dr. Selle's Process for Natural-Colour Photography: Dr. Neuhaus.

WEDNESDAY, DECEMBER 9.

SOCIETY OF ARTS, at 8.—Mining at Great Depths: Bennett H. Brough.

SANITARY INSTITUTE, at 8.—Soils and their Suitability for Sewage Farms, with the *rôle* of Bacteria in Sewage Disposal: Dr. Samuel Rideal.

THURSDAY, DECEMBER 10.

ROYAL SOCIETY, at 4.30.—On Prof. Hermann's Theory of the Capillary Electrometer: G. J. Burch.—An Attempt to determine the Adiabatic Relations of Ethyl Oxide: E. P. Perman, Prof. Ramsay, F.R.S., and J. Rose-Innes.—Experiments in Examination of the Peripheral Distribution of the Fibres of the Posterior Roots of some Spinal Nerves, Part II.: Prof. Sherrington, F.R.S.

MATHEMATICAL SOCIETY, at 8.—A Discovery in the Theory of Compound Denumeration: Prof. Sylvester, F.R.S.—On the Stationary Motion of a System of Molecules having Finite Dimensions: S. H. MODERN PSYCHOLOGY.

Analytic Psychology. By G. F. Stout. Two volumes. Pp. 289, 314. (London: Swan Sonnenschein and Co., Ltd., 1896.)

An Outline of Psychology. By Edward Bradford Titchener. Pp. vii + 352. (New York: The Macmillan Company, 1896.)

MR. STOUT'S "Analytic Psychology" is a very important and valuable contribution to the study of mental processes. With the exception of Dr. Ward and Prof. James, no other English writer in modern times has treated the subject with as much originality and freshness as the present editor of *Mind*. The two volumes before us are, however, only introductory to further work from the same hand, to which we shall look forward with special interest. Problems of genesis and development are not examined in the present work, which treats only of fundamental questions connected with analysis and definition. Yet the reader who peruses Mr. Stout's powerful criticism of current doctrines will at once realise the importance and difficulty of these preliminary questions. Unfortunately the science of mind is still at an inorganic stage. Its authorities are still in conflict on the most elementary questions of classification, terminology, method and scope. We are bound to say that the author's method of solving time-honoured puzzles, highly suggestive as it is, raises almost as many difficulties as it meets. This hardly detracts from the merit of the work, which we appreciate unreservedly. Students of psychology need not be reminded of the troublesome questions which are inevitably thrust into the foreground at the beginning of every text-book or treatise. The antithesis between knowing and feeling, the limits of consciousness, the conception of activity, the function of introspection—these are some of the well-known problems which our author handles in novel manner. Undoubtedly the most striking innovation in terminology and method is the author's introduction and use of the contrast between what he terms *noetic* and *anoetic* consciousness. Modifications or contents of consciousness are broadly contrasted, according as they do or do not refer to an *object;* the former are called *noetic*, the latter *anoetic*. This distinction, of course, roughly corresponds to distinctions variously formulated by previous writers. What amounts to nearly the same as the anoetic consciousness has been vaguely and variously styled pure sentience or feeling, or has been obscurely relegated to the regions of sub-consciousness. But Mr. Stout throws light on many obscurities of exposition by his thoroughgoing application of this antithesis between anoetic and noetic. Thus previous writers have identified the *object* of thought and attention with the *presentations* entering into the current of conscious experience. Mr. Stout definitely opposes *presentation* and *object*. The *object* to which noetic consciousness refers cannot, from the nature of the case, be a present modification of individual consciousness. All thought and perception involve reference to something which, as it is meant or intended, is other than the thinker's own conscious content. This view connects itself with every detail of analysis propounded by the author, and can hardly be appreciated without reference to his treatment of other topics, such as the conception of mental disposition, the relation of apperception to noetic synthesis, the interconnections of thought and conation, the development of desire and volition. A remarkable unity and harmony characterise the treatment of all these questions, in consequence of the very careful definitions and distinctions given at the outset. The chapter on "Relative Suggestion" is, perhaps, the most interesting and original in the book. It supplies a much-needed corrective of older associationist views, and an exposition of the link between mere cohesion of ideas and the processes of constructive thought and imagination. In another most important chapter, the conception of mental activity is very ably defended against Mr. Bradley's attacks, and in opposition to some statements of Prof. James and others. Mr. Stout is a champion of the doctrine of apperception, as propounded by Herbart and his followers. But his own modifications of this doctrine are considerable and important. The chapter on "Noetic Synthesis" prepares the reader for the author's special views on this point. Noetic synthesis involves a distinct content of consciousness, viz. "the apprehension of a whole which determines the order and connection of the apprehension of the parts." But "when we consider a noetic synthesis not merely as involved in this or that conscious process, but as a mode of mental grouping which persists as a disposition when it has ceased to operate in actual consciousness, we have the idea of an apperceptive system." Under apperception we investigate the gradual growth and differentiation of new phases of noetic synthesis. Again, the view of the relations between apperception and attention is a special feature of Mr. Stout's doctrine: "Whereas attention is an attitude of consciousness towards a presented *object*, apperception is a process of interaction between *presentations* or *dispositions*." His position on these points is worked out in most instructive detail, which it is impossible for the reviewer to indicate. Finally, Mr. Stout gives a prominent place to *belief*, as a fundamental attitude of consciousness towards its object, and propounds an original doctrine of pleasure-pain, which is supported by subtle and suggestive reasoning.

The general treatment is rendered especially instructive by the large number of well-chosen illustrations of mental processes analysed at first hand. The psychological standpoint is perfectly preserved throughout, and we do not find a substitution of physiological or physical hypotheses for genuine psychological analysis. In spite of the marked originality of style and exposition, at no point is the tone unnecessarily antagonistic; and suggestions are accepted from writers of every school of thought, with only such modification as is necessary to adapt them to the author's general scheme.

Prof. Titchener's "Outline of Psychology" is written with admirable clearness. The results of experimental psychology are expounded in a style both attractive and simple. The author's own views are supported by careful reasoning, and at the same time the beginner is not overwhelmed with any superfluous con-

troversial matter. Rules for experimental and introspective research and illustrations of their application are arranged and expounded in a thoroughly methodical manner. The author admits only two ultimate kinds of "conscious elements"—sensation and affection—definitely rejecting *activity* as a third conscious element. Space is devoted to what may be called "Numeral Psychology," *i.e.* the estimate of the total number of different conscious elements. The method, of course, is to ascertain the just discriminable difference. Underlying this whole procedure there appears to be a logical fallacy, or at least a difficulty which modern text-books entirely ignore. Thus, suppose that *a*, *b*, *c*, *d*, *e*, *f* . . . is a series of measurably different physical stimuli, and A, B, C, D, E, F . . . the sensation-processes supposed to correspond with the stimuli. Suppose, further, that *a*—*d* or A—D represents the just discernible difference. Then, by hypothesis, sensation A *is* just distinguishable from sensation D, while sensation B is *not* just distinguishable from sensation D. Hence sensations A and B have opposite predicates, and therefore they are different, although, by hypothesis, they are consciously undistinguishable. Now in "counting" the number of sensation-elements, it is always assumed that difference means the same as distinguishableness. But that this leads to logical contradiction is obvious from the above, while it is in flat opposition to Weber's logarithmic formula, which implies that a continuous variation of stimuli corresponds to a *continuous*—not discrete—variation of sensation. The author's mode of distinguishing (1) sensation, whether peripherally or centrally aroused, (2) perception or idea, and (3) the association of ideas, seems decidedly original and worthy of careful consideration. No doubt he is right in making the distinction between (1) and (2) depend on the absence or presence of objective significance; but it seems unsatisfactory to offer only a "biological reason" (p. 183) for the unity possessed by the perceptual or ideal complex of sensations. Again, in treating of conception, judgment and reasoning, no higher mode of intellection seems to be recognised than association. We feel ourselves carried back to the dark ages of psychology when we read (p. 301)—

"We speak of a comparison of two impressions when the ideas which they arouse in consciousness call up the verbal associate 'alike' or 'different.' . . . We have in this process of comparison or discrimination, then, a case of verbal association."

We are curious to know whether the words "alike" or "different" have any significance; and, if so, whether this significance is an object of conscious apprehension or not. Other passages point to similar defects, owing to the author's confidence in sensation and association as the sufficient materials for all intellectual processes. It is true that the author avoids many of the fallacies of the old mechanical view of association, and many parts of his exposition are unexceptionable in the light of modern criticism. But the characteristics of the book that are to be most highly commended are clearness, simplicity, wealth of illustration, and, in general, adaptation to the needs of the beginner who requires to be placed *en rapport* with the latest results of experimental psychology. W. E. JOHNSON.

A MANUAL OF DAIRY WORK.

The Book of the Dairy. Translated from the German of W. Fleischmann by C. M. Aikman and R. P. Wright. Pp. xxiv + 344. (London: Blackie and Son, 1896.)

NO branch of practical agriculture has made greater progress during the last quarter of a century than that which may be broadly described as dairy farming. The evidences of this advance are to be sought, however, not so much in the operations antecedent to the production of milk as in the processes employed in its after treatment. In making this assertion, we do not overlook the improvements which dairy farmers have effected in the housing, feeding, and general management of milch kine. But these have resulted mainly from the intelligent modification of time-worn practices, whereas in the manipulation of milk, either for sale as such, or for manufacture into butter or cheese, there has been ample scope for modern ingenuity in the introduction of novel methods. The cow remains to-day what she has been for ages—a physiological implement for the production of milk, and we may recall the words of Charles Dickens, "If civilised people were ever to lapse into the worship of animals, the Cow would certainly be their chief goddess." Cows, especially of certain breeds, have, by judicious selection exercised by the breeder, been greatly improved in their milk-yielding capacity, in respect both of quantity and of quality. But there is no essential distinction between the cows of to-day and those which furnished milk to our Saxon ancestors—the difference is only one of degree. On the other hand, the change in the methods and appliances of the dairying industry, even if the comparison be made with so recent a period as only thirty years ago, is so profound that it may well be termed revolutionary. The displacement of the old system of cream-raising by the rapid work of the centrifugal separator, the rational use of micro-organisms in the ripening of cheese, the sterilisation of milk in the destruction of tuberculous and other germs, the direct and almost instantaneous manufacture of butter from fresh milk, are only a few illustrations of what has been accomplished in very recent years. With such changes constantly in progress an extensive literature has sprung up around the industry of dairying, and many notable works upon the subject have been published in the English, French, German, and Danish languages.

Of the dairying experts of Germany, no one occupies a higher position than Dr. Fleischmann, of Königsberg, and no doubt many readers will welcome an English translation of his well-known manual of the science and practice of dairy work, which Messrs. Blackie have issued in a style deserving of commendation. The first chapter deals with the secretion, properties, and composition of milk, and discusses the defects which give rise to bitter, coloured, ropy, lazy, or sandy milk. The extraction, immediate sale, and testing of milk form the subject of the next chapter, which is partly commercial in its scope. For the third chapter the translators have chosen the not very intelligible title of "Milk in its relation to micro-organisms, dairying, and bacteriology." Butter-making and cheese-making are the respective subjects of the two succeeding chapters, which are

followed by one on the "Preparation of keeping milk, fermented milk, and the bye-products of milk." The economic aspects of dairying are next dealt with, and a concluding chapter is devoted to margarine and margarine cheese.

The definition of milk, with which the book opens, seems to lack those qualities of precision which should characterise a definition. What kind of notion would the following words convey to a reader who knew nothing about milk?—

"By milk, in the widest sense of the term, is understood the secretion of the special glands of the female mammal. It is a white, opaque liquid, of the character of an emulsion, with a faint odour and a slight flavour; and it is produced during a longer or shorter period after parturition. It consists chiefly of water, fat, casein, albumin, milk-sugar, and mineral salts, and is specially adapted for the sustenance of the young."

That milk "consists chiefly of water" we know; but had the translators been on the alert, they would have suppressed the word "chiefly" in the foregoing passage. The difficulties of translation, indeed, are exemplified in various unhappy phrases, as, for instance, when keeping milk is defined as milk which "possesses the property of being able to keep."

A point about which there has been much controversy—the existence or not of an enveloping membrane upon each of the fat globules in milk—is dealt with emphatically enough:—

"The fat globules are not surrounded with a membranous envelope. Owing to the action of molecular force, the little globules are surrounded by a thin watery covering of serum, and act very much as if they were actually surrounded by a membrane."

Dairy farmers, and many who are not dairy farmers, will be puzzled by a statement, which apparently has been casually dropped in on p. 21, concerning the impetus which a globule receives through its weight and centrifugal force; there is at least novelty in the idea of the "centrifugal force" of a fat globule of milk. On p. 46 is another statement which will certainly startle all experienced feeders of dairy cattle; it is to the effect that "milk cows must not be fed with beans, peas, lupines, pea-straw." Of feeding with lupines we do not know much in this country; but as to the other materials, a footnote shows that even the translators felt uneasy, and it is regretable that they did not suppress the passage. The author recommends, in the winter feeding of butter cows, the moderate use of beet, in conjunction with other foods. This, of course, is perfectly intelligible to a German farmer; but the translators should have added that for all practical purposes the English mangel is competent to take the same place in the food as the German beet. The feeding of cows, indeed, is a subject which might well have been treated more fully. This section contains a statement which we cannot forbear quoting, for it relates to a matter of as much practical interest to the dairy farmer as of scientific interest to the physiologist. On p. 42, the author says:—

"There can be no doubt that, in the case of cows yielding a large amount of milk, the fat derived from the food is utilised for the formation of milk-fat."

The nature of the few criticisms we have made should render it obvious that a free translation and adaptation of Fleischmann's work would have been more valuable than the very literal translation that has been provided. Many of the woodcuts—of which there are eighty-five, besides half-a-dozen full-page plates—are different from those in the German original, and it is matter for regret that the same latitude was not allowed in connection with the text. It cannot be doubted that the translators possess the knowledge and skill essential to the production of a serviceable adaptation, and their description of—for example—the manufacture of Cheddar cheese in this country would probably have differed considerably from that of which they have laboured hard to furnish a word-for-word rendering. Viewing the book as a whole, it is not one to put into the hands of a beginner. A discriminating reader, however, who already possessed some knowledge of the subject, would peruse its pages with profit.

OUR BOOK SHELF.

Elementary Geology. By G. S. Boulger, F.L.S., F.G.S. Pp. viii + 180. (London and Glasgow: William Collins, Sons, and Co., Ltd., 1896.)

Dr. W. S. Davis' "First Book of Geology" has been rewritten and revised throughout, and transformed by Prof. Boulger into the text-book now under notice. The chief criticism we have to offer upon this metamorphosed volume—and the criticism applies to most elementary text-books—is that details are dealt with much too early. Four pages in the present volume are devoted to general remarks on the objects and methods of geology, geological evidence, and divisions of the subject; and about five pages to descriptions of the form and size of the earth, terrestrial movements, the nebular theory, the probable condition of the interior of the earth, and the cause of the Glacial period. The nature of the descriptions may be gathered from the statement of the limited space occupied by them. Of this brief treatment of large subjects we do not, however, enter a complaint, for the book is intended principally for pupils connected with the Department of Science and Art, and, regretfully though we say it, these pupils like concentrated essence of facts, which can be assimilated with the smallest possible mental exercise. Such readers may develop a mild kind of interest in the first nine pages of the book; but then comes the *pons asinorum* of text-book geology—the account of rock-forming minerals and their distinctive characters. Why should such a paragraph as the following be put before a beginner in geology?

"Sulphur unites with many metals to form *sulphides*, including the abundant iron-pyrites (FeS_2), and many important metallic ores, such as chalcopyrite, galena, and blende, ores of copper, lead, and zinc respectively. Chlorine with sodium forms the abundant *chloride*, common salt (NaCl). Iron forms two oxides, the *ferric oxide* (Fe_2O_3), which occurs as hæmatite and hydrated as limonite, both important ores, and the *ferrous oxide* (FeO), while both occur in the black oxide, magnetite (FeO, Fe_2O_3, or Fe_3O_4). The oxide of aluminium (Al_2O_3) is called *alumina;* that of calcium (CaO), *lime;* that of sodium (Na_2O), *soda;* that of potassium (K_2O), *potash;* and that of magnesium (MgO), *magnesia;* and these oxides and those of iron are, when in combination, known as *bases*. In combination with acids they form *salts:* with silicic acid (H_2SiO_3), silicates; with carbonic acid (H_2CO_3), carbonates; with sulphuric acid (H_2SO_4), sulphates. The majority of rock-forming minerals are silicates."

It seems to us to be a great mistake to assume that young students of geology possess sufficient know-

ledge of chemistry to comprehend such a list of names and formulæ as is contained in the foregoing quotation. A book constructed on educational lines should not so readily run into details, and should never do so without sufficient explanatory text.

Taking the book generally, it is better than many others of its class, but little more can be said for it. Every geologist will, however, endorse the prefatory remark that "no text-book, however large, can impart an adequate knowledge of geology unless supplemented and controlled by actual contact with the facts of nature."

Annual Report of the Geological Survey of Canada. New series. Vol. vii. 1894. (Ottawa: S. E. Dawson, 1896.)

THIS large volume of over 1200 pages contains, in addition to the Summary Reports of the operations of the Survey for 1894, seven detailed reports on certain portions of the Dominion, and is accompanied by eleven geological maps.

The Summary Report shows that geological work is being carried on by the large staff of the Survey in every part of the Dominion. Especial mention is made of the trial borings now being put down at Athabasca Landing in the North-west Territories, where there is good reason to believe large supplies of oil will be obtained from the Devonian rocks at a depth of about 1500 feet. An account is also given of the recent advances in the development of the mining industry of British Columbia, where of late years such extensive mineral deposits have been discovered, as well as of the explorations in the Labrador peninsula carried out by Mr. Low, who has discovered in this inhospitable region deposits of iron ore which are believed to surpass in size any that have hitherto been discovered in North America.

Of the special reports, two deal with British Columbia: one, by Dr. G. M. Dawson, containing a description of a portion of the interior plateau of that province in the Kamloops district; and the other, by Mr. R. G. McConnell, giving an account of the explorations of the Finlay and Omineca Rivers. These are followed by a report on the country about Red Lake, in Keewatin, by Mr. Dowling. The fourth report is by Dr. R. H. Ells and Dr. F. D. Adams, on a portion of the province of Quebec, comprising the island of Montreal and a part of the eastern townships to the south and east. Mr. Chalmers then describes the superficial geology of the provinces of New Brunswick, Nova Scotia, and Prince Edward Island; while, in the concluding reports, Dr. Hoffmann and Mr. Ingall treat of the chemical work of the Survey and the mineral statistics of the Dominion respectively. Dr. Dawson's report contains an excellent description of the interior plateau of British Columbia from a geological and geographical standpoint. The very extensive development of the Cambrian in this part of the Dominion is noted, as well as the continued volcanic activity from Cambrian to recent times, the volcanic materials, at a very modest computation, having a thickness of 20,000 feet.

Poems of George John Romanes. Pp. xvi+108. (London: Longmans, Green, and Co., 1896.)

THIS small volume consists of a selection from the poems of the late Mr. George John Romanes. It contains two long poems entitled "A Memorial Poem to Charles Darwin," and "A Tale of the Sea." Both are fine and of a striking quality. Sonnets form the rest of the book, and in many of these the naturalist, as well as the poet, is revealed to us by the accurate descriptions of nature, and the many references to objects and phenomena connected with science. We may add that Mr. T. Herbert Warren, President of Magdalen College, Oxford, has written the introduction, in which he gives a short biographical sketch of the author.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Pound as a Force, and the Expression of Concrete Quantities generally.

WHAT is Prof. John Perry tilting at in his educational tirade on page 50 of your issue for November 19? To judge from a friendly post-card asking me to reply, he seems to imagine that he is attacking physicists; but apart from this private information I should have imagined that he had in his mind a nearly extinct type of Cambridge text-book, and some—I do not know how many—belated schoolmasters.

Let me assure him, speaking no doubt for others but of most knowledge for myself, that if any student of mine could only express force in poundals and energy in foot-poundals I should be as disgusted as he himself.

One of the first things a student of physics has to learn is that no numerical exercise is fully worked out until it is expressed in units to which he and others are accustomed, and of which they can "feel" the magnitude. As an intermediate step such an expression as 10^7 F.P.S. or C.G.S. units is legitimate enough, but the final answer should be expressed in hours, or days, or other appropriate unit, if time is the subject; in miles, or millimetres, or inches, if it be a length; in hundredweights, or tons, or grammes, or pounds weight, if it be a force; and in ergs, or foot-pounds, or kilogramme-metres, or Joules, or even in kilowatt-hours, if energy be the quantity under consideration.

An educated student speaking to a workman should use the colloquial unit of the shire in which the works are situated; in addressing a foreign correspondent (if orders ever reach this country now from Germany, for instance), he should employ a less insular and more international system; he should, in fact, have no difficulty in making a specification in any conventional system of units to which he has the key.

Prof. Perry asks us to limit ourselves to the C.G.S. system on the one hand, and to the British gravitational system on the other; with those he thinks we can jog along, but with any others we are liable to make mistakes. Does he call that education? If this is the type of "finished engineering student" he is accustomed to, no wonder they "cannot get into works without paying high premiums." (Parenthetically I wonder what premium the Hopkinsons paid in order to be taken into works.) Surely he would not say to a youth training as a banker, "despise all *thalers* and *marks* as trumpery, let us have nothing but good English pounds, and then we shall know where we are, and make no mistakes."

Ah, but, he will say, these units are appropriate to different countries, and you must be able to adapt yourself to the coinage in travelling. Even so! Yet he would seek to limit the physicist, whose range of travel is as wide as the universe. Has he forgotten the variety of subjects with which physical science is concerned? Sometimes there is astronomical energy to be expressed, sometimes thermal, sometimes chemical energy, and sometimes electrical. Would he be content that his educated engineer should be able to express these in nothing but a unit appropriate to the pumping of water out of a mine? When an engineer sees the expression $\frac{1}{2}mv^2$ (which, by the way, he seldom does see; it is generally $wv^2/2g$ in his books, as if gravity were concerned in every transaction of the universe), he is not to think of it straight as momentum multiplied by velocity, or even as inertia multiplied by the square of a velocity, or as energy in any of its protean forms; he is to think of it as a number of foot-pounds. He cannot receive the data in any units whatever and bring out the answer in any other units whatever, one set for the French motor car driver, and another set for the owner, and another for the electrician; no, but he is to say, I must first have the mass given me in pounds, or I may make a mistake; then I must divide the number of pounds by a mystic number, viz. 32·18, in order to bring them to the particular kind of practical unit of inertia which my revered instructor so highly prized; and then I must be told the number of feet per second contained in the velocity (I should be confused by a specification in telegraph posts per minute or kilometres an hour); after that I can do the arithmetic quite nicely, and I remember that the answer always comes out in foot-pounds, which gives no trouble to any one; thus shall my employer not suspect me of being college-

taught, and I shall gain advancement in the profession to which I have reason to believe that I was "heaven-born."

Prof. Perry seems in a parlous state, between "friends" who "worship a German soul-destroying fetish," and foes, "academic enemies," who object to the use of the term centrifugal force! Now, I wonder who they are, and why they object to this term. There was once a type of text-book wherein kinetic problems were treated statically, and the centrifugal force exerted by the revolving body was depicted in the diagram and reasoned about as if exerted *upon* the body; does Prof. Perry count among his enemies those who fought against this misleading practice? Again, there appear to be other foes who will not let him use the pound-weight as a unit of force in peace: but is he not a victim of some delusion? A pound-weight or an ounce-weight or a ton-weight are extremely handy force units for actual application, or for calculations dealing with heavy bodies at rest; and an engineer is largely concerned with the statics of heavy bodies, as Prof. Perry truly says, why then should he not use the appropriate unit? Again, when he is pumping water or lifting weights he finds the foot-pound or the kilogram-metre a handy conventional abbreviation for an energy unit: it must be some churl who objects, not a physicist. Was the foot-pound repugnant to Joule? All that a physicist is anxious about in connection with units is that they shall be used accurately and intelligibly, he knows that they are mere agreed-upon conventions, of which some are more generally convenient than others, and he tries to define them conveniently for the practical man's use, and to retain visibly all essential factors; but he is careful not to identify the number of units, or any other mere measure of the thing, with the thing itself.

This last is a point on which some, I fear, are still not clear. Nobody makes this mistake with regard to matter. It can be filed and twisted and heated, &c., it never runs the risk of being thought of as a number of units. Energy is less tangible, and runs more risk of being so maltreated; while as to force, a few philosophers can now be found who teach that force is a mere measure of the time-rate of change of momentum. I wonder if they would say that to a man on the rack!

As to units, I have no objection on principle to hogsheads or kilderkins, but I should seriously object to a student who held that while a pound was a force, a kilogramme was a mass, and at the same time was willing to believe that a kilogramme equalled 2·2 pounds.

To identify weight and mass is barbarous, to denote their units by the same name is unwise, to lose sight of the dimensions of g, and treat it as merely equivalent to 32·18, is illiterate. The whole matter can be put in a nutshell by saying, w and g are both vectors, parallel vectors, and m is their (scalar) ratio.

There are, in fact, three distinct things, all capable of being denoted by such a word as "ton" in common parlance. There is the mass or quantity of material, which concerns us in dealing with markets; there is the inertia or reaction to force, which is important when we are dealing with acceleration; and there is the etherial stress, due to the neighbourhood of the earth, which drives the two pieces of matter together unless they are propped apart.

The last-mentioned curious and ill-understood deportment of two bodies is interesting in itself, and appeals directly to the engineer whenever he has to increase the distance between the earth and another body; it has, indeed, laid such hold of his imagination that he has begun to think it the most fundamental property of matter, and is willing to identify it with the actual substance of the smaller of the two bodies: he is even willing to identify it with its inertia-reaction, especially after division by some arbitrary number suited to himself, his parish, and his work.

May I tell Prof. Perry what is at the root of the perennial debate between engineers and teachers of mechanics?

It is the subject of *acceleration*. An engineer's bodies are nearly always either at rest or in uniform motion, their accelerative stages he is usually able to ignore. The portion of mechanics which serves his need is, therefore, simple enough, and he rebels against more. But the teacher perceives the treatment of acceleration to be the key to mechanics in its higher sense—viz. as an introduction to physics, and as the foundation science of the material universe. He emphasises the idea of inertia, therefore, and sets problems in the accelerative stages of motion, because he knows that there lurk the difficulties and there the soul of the science. He hopes that an engineering student, in these days of a wider application of physics than was common half a century ago, may be willing to learn something more than the mutilated fragment of science which serves for commercial purposes. Sometimes he hopes, but at present he hopes in vain, that the student's own more immediate superiors will refrain from encouraging him in half-knowledge and casual omissions, and the testing of everything by immediate pecuniary results. He hopes that the Engineer, although very busy in his proper domain, may have a sympathetic faith in a larger training, and not inadvertently snuff out any nascent clearness of ideas by ranging himself alongside our true and only natural foes, the powerful obstacles of ignorance, idleness, and prejudice.

Vast improvements in school teaching are possible, and should be strenuously urged. Prof. Perry is now, I suppose, head of the Government teaching of mechanics in this country, and his educational views are no individual concern; but let him discriminate. There is plenty of scope for his warning voice and vigorous sense of the need for contact with realities at every stage. Let him inveigh against wasting time over the fifth book of Euclid, for instance, (if any body now does) and other extravagantly refined conceptions too subtle for the majority of people who have so much to learn of which their teachers are ignorant, let him urge teachers to express common things easily and not only in a scholastic jargon misunderstanded of the people; but, *maxima debetur pueris reverentia*, let him urge clearness of idea and accuracy of speech on all who deal with the junior student. These should not call different things by the same name; these should not be satisfied with lazy and incomplete specifications with essential factors omitted; these should grasp the real and the essential and distinguish from the arbitrary and the conventional, emphasising the one and treating lightly the other, and not considering either themselves or their pupils heaven-born geniuses because unable to grasp fundamental principles.

Above all I ask Prof. Perry to believe that the physicist means something solid when he asserts that formulæ need not all be of the engineering pocket-book type, the type where the units must be stated before an equation is intelligible or useful. Such formulæ are in truth a mere mixture of arithmetic and convention, very useful in their place but not really applied mathematics at all.

Misapprehension on this point is at the bottom of the needless and hampering introduction of units by engineers into every equation; and at the risk of being tiresome, I must once more illustrate the difference between an arithmetical formula of the engineering pocket-book type, and a real mathematical equation, by some simple example. The following may or may not be a sailor's rule, but it is an approximately true and handy one:—

Your height above the sea-level expressed in feet, if square-rooted and multiplied by $\frac{3}{4}$, gives the distance of the visible horizon in miles.

A handy rule I call it, and no more. Your ship's captain who knows that alone is in the position of your engineering student who, whether taught at college at not, has been taught badly, and has not brains enough in himself to supply the deficiency.

The equation, of which the above rule is a convenient but specialised and mutilated version, is $2\,R\,h = d^2$. My readers must pardon the triviality of the illustration, and the fact that it is not accurate to the second order of minutiæ, because none of these things matter to my present purpose. The principle I am urging is illustrated well enough by the two points, (1) that the size of the earth, which was omitted from the rule, makes its appearance in the equation, and it is obviously a vital element in the problem; (2) that the equation requires no specification of units, but is complete in itself, and is independent of every system of units that ever were devised; h is not the number of feet, or of metres, or anything else, it is the actual height; d is not the number of miles or of inches to the horizon, but it is the distance itself; and similarly $2\,R$ is the diameter of the earth, and not any numerical specification of that diameter. The thing, so far as it is true at all, is true from the bottom upwards and entirely true, number and dimensions and everything, with no factor omitted, or slurred over, or suppressed; that, and not the C.G.S. or any other trivial convention, is what is meant by absolute measure. *Ex uno disce omnes.*

Using this trivial example as a type or fable, I say that the college-taught student who knew $2\,R\,h = d^2$, or its equivalent Euc. III. 36, but could not apply his knowledge to estimate

the distance of an iceberg or a hull, though he spent his days at sea, would be an ass, capable of bringing his college-training into well-merited contempt. Also, that the youth who could apply his pocket-book rule, without knowing or seeking the reason of it, would be a useful ignorant machine, creditable enough in the forecastle, passable amidships, but out of place on the bridge, and not to be desired as the product of any educational institution whatever. OLIVER J. LODGE.

University College, Liverpool.

FEW physicists will allow to pass without protest some of Prof. Perry's observations appearing in NATURE of November 19, however reluctant they may be to raise a fresh dispute on the evergreen subject to which they refer. So far as one can gather, the Professor has long since adopted one of the many ways in which the fundamental relation of dynamics may be regarded, and works himself up into a stage fury because the majority of modern physicists regard the question in a somewhat simpler and more correct way.

Prof. Perry has an admirable fondness for kindergarten methods. Let then a beginner be armed with a simple spring balance, made, say, with elastic cord, a small waggon on wheels, a number of masses, a rule, and a clock. By a few simple experiments on a level floor or table, such as one of Prof. Perry's heaven-born engineers should delight in, he can soon be made to convince himself, independently of the units in which he measures, that the rate of increase of velocity a of a body acted on by a force is roughly proportional to the force and inversely as the quantity of stuff in the body. He will thus readily grant, in a general way, that $a = k\frac{F}{m}$, where k is some constant, and will be in a position to understand the absolute truth of this relation later on. If he is an English student, he will have no objection to measure distances in feet, time in seconds, the stuff that he puts into his waggon in pounds, and perhaps the pulls that he applies to his waggon in pounds weight. He will surely admit the propriety of expressing a in (feet per second) added on per second—in the unit sometimes called, on the suggestion, I think, of Prof. Lodge, the "hurry." k then becomes the number g, and the experimenter will easily convince himself that with these units it is about 32. If he is a *bonâ-fide* beginner, I doubt if he will ever make a set of experiments in physics which will afford him more instruction, rough though his results may be.

But with these units k is not quite constant: not *absolutely* so even if the standard pound is kept in London, Prof. Perry notwithstanding. And, incidentally, is an engineer who loads the lever of his safety-valve with a bucketful of bricks in other latitudes in just the same position as if he did the same in London? Not that I intend to imply that variations in g matter much to the professional work of men who (very properly) compound for any little discrepancy between their calculations and the ways of nature by liberal use of factors of safety, of trifling magnitudes such as 10.

We pass then to the conception of absolute measurement, the interest and value of which are not reserved exclusively for those who use the C.G.S. system, but exist in all systems. We can make $k = 1$, and write the fundamental equation in the form $a = \frac{F}{m}$, most readily by adopting either of two conventions, (1) by expressing matter in pounds and forces in terms of a unit the gth part of a pound weight (the poundal); or (2) by expressing forces in the approximately constant unit the pound-weight, and matter in a new unit, also approximately constant, consisting of g pounds. Of these two alternatives Prof. Perry chooses the last. It is also the worst, for four reasons at least, viz.:

(1) That the system is needlessly complicated, through demanding the conception of two standard portions of matter; namely, the standard pound-mass whose weight is the unit of force, and the "engineer's unit" of mass or inertia (*teste* Perry) of 32·18 pounds.

(2) That the unit of force is variable or vague, unless careful reservations are made.

(3) That the unit of mass is ditto, ditto.

(4) That a majority of those who use any such system at all, already use, largely for the above reasons, the other convention, involving the idea of the poundal.

And no amount of abuse or sophistry from the non-orthodox will get over the fact that so long as we have as standards a foot, a second, and a lump of matter that we call a pound, and so long as we think of forces as we do at present, that force which, acting on that lump of matter, would give it an acceleration of one (foot per second) per second must always have a singular interest for us, entitling it to rank as a unit even with those who personally may be content to reckon the forces with which they have to deal in some other way.

But why should Prof. Perry be so dissatisfied? His students make no mistakes, and by the adoption of his shibboleth the very tender blossoms for whom he pleads will be enabled to produce luxuriant crops in the profession for which they seem so unfit. Can it be that in attempting, for instance, to become electrical as well as mechanical engineers, they find a horrible gulf between the artificial system they know and the C.G.S. units they will have to use?

And what right has the Professor to assume that all real engineers regard the question as he does? I wonder what percentage actually do so. On what platform, for instance, is Prof. Greenhill just now, to whom the idea of mass is as if it were not, absolute measurement an accursed thing, and, above all, that relic of the dark ages, Prof. Perry's 32·18 lb. unit, Anathema? If only these champions of rival heresies can be persuaded to demolish one another, there will be for the orthodox a great peace. M. J. JACKSON.

Oxford, November 24.

MAY I, as a teacher of physics, many of whose pupils enter the engineering profession, be allowed to say a word in my own defence in reply to Prof. J. Perry's scorn, expressed in an article, "The Force of One Pound," in NATURE of November 19, vol. lv. p. 49, for those who, like myself, teach my pupils the use of the poundal in dynamical calculation.

I am sure that Prof. Perry agrees with me in looking at an absolute system of measurement, whether British or metrical, as the only logical one, and where for practical purposes change of unit has to be made, there seem to me to be two courses open: (1) to make such a change in one, or all, of the fundamental units and work *ab initio* with these changed units; or (2) to work in absolute units, converting the absolute into the practical unit, by means of multiplication by a suitable factor, or, in other words, to introduce a constant of variation, different from unity, into our equations. I prefer to adopt the latter alternative where units of force have to be expressed in practical pound-weight.

Prof. Perry seems to suggest a third course, and asks us to begin with an absolute system in which the unit of force is to be one of our absolute units, the other two presumably being the ordinary foot and second. Of course, a system of theoretical dynamics could be built upon this basis, but to teach it, as we are invited to do, side by side with the C.G.S. system, would confuse the mind of any pupil unless he were an engineering student.

But there is another branch of engineering science in which exactly the same thing has to be done, namely, electrical science. Here, too, we have a system of equations which are invariably expressed in absolute C.G.S. measure, that is, in terms of units not practically in use. Here we may again either work out anew the formulæ, choosing as unit of length the quadrantal arc of the earth (10^9 cm.), and as unit of mass the 10^{-11} gm., or, as I prefer, employ the ordinary formulæ and multiply the result obtained from it by the appropriate factor when wishing to reduce the result to practical volts or amperes; or is there still a third method in which volts and amperes become the fundamental units in terms of which lengths and forces have to be measured? L. CUMMING.

Rugby, November 23.

Recent Work on the Madreporarian Skeleton.

I SHOULD like to draw attention here to a paper just published on the skeleton of Madreporaria, by Dr. von Koch, Professor of Zoology in Darmstadt, in the Gegenbaur *Festschrift*. Some time ago, in November 1895, an "abstract" was published by me in the *Proceedings* of the Royal Society, vol. lix., embodying the results of a full paper entitled, "Microscopic and Systematic Study of Madreporarian Corals." The full paper, with very numerous illustrations, will be published this month in the *Philosophical Transactions*. Prof. v. Koch does not mention this abstract in his reference-list of literature. It will be all the more interesting to those who may happen to be familiar with both papers to have set before them the more important points

wherein Prof. v. Koch's new paper was anticipated by mine of last year, and serves to confirm my published statements.

One of the advances made in my "abstract" was the recognition of lamellar structure throughout all the various parts of the Madreporarian skeleton. And this is the main kernel of the skeletal structure as now elucidated by Prof. v. Koch. For example, he writes of the epitheca! "foot-plate" in the young coral :—"This first thin little plate is afterwards more and more thickened by more or less plainly laminated deposits (*Geschichtete auflagen*) of new skeletal substance from the ectoderm" ("Das Skelett der Steinkorallen," in *Festschrift*, für Carl Gegenbaur ii., p. 253). I give the translations from Prof. v. Koch's paper as literally as possible.

In the treatment of *septal* structure the results obtained by Prof. v. Koch coincide in a very great degree with statements previously published in my "abstract," as will appear from the parallel columns below.

"ABSTRACT," OGILVIE.
(*Proceedings* Roy. Soc., 1895.)

The opacity of the "primary streak" is explained as due to "a larger amount of organic cell-material" originally present near the median plane—*i.e.* at the growing edge—of the septum. Then the passage continues : "Sections show that the fibro-crystalline structure of the septum is the same throughout its whole thickness, essentially that of a double system of thin calcareous lamellæ, either smooth or fluted, and corresponding to a deposit from opposite flaps of an invagination (*l.c.* pp. 11–12).

Regular *curves* or *lines of growth* are evident on the septal surfaces marking the intervals between successive growth-periods. The space between two growth-curves or lines on the septal surface represents the part of the septum built up in one growth-period, and it has been called by the author a septal *growth-segment* (*l.c.* p. 12).

In certain cases "the fibro-crystalline deposit is radially symmetrical around ideal trabecular axes in the median septal plane." As examples, the markings perpendicular to the spiniform-toothed edge of the Mussa septum are quoted, and reference is made to the striæ of Galaxea septa, the ridges on the septa of Fungia, &c. (*l.c.* p. 11).

"DAS SKELETT DER STEINKORALLEN," V. KOCH.
(*Festschrift*, für C. Gegenbaur, 1896.)

Regarding the structure of the septa, . . . the first-formed parts, "primary streaks" (Primärstreifen) show a more irregular structure and distinguish themselves usually by greater opacity from the "stereoplasm" or secondary part lying on either side, whose crystalline elements are more or less perpendicular to the "primary streaks." One can often plainly recognise lamination (Schichtung) in these secondary deposits (Auflagen) (*l.c.* p. 255).

The fairly simple and easily recognisable structure thus described is, as a rule, somewhat more complicated by the presence of *growth-streaks* (*Anwachsstreifen*) alternately darker and lighter lines, which appear in sections parallel to the surface of the septal edge, and are caused by differences in the crystallisation of the layers of thickening laid down one after the other (*l.c.* p. 256).

"Frequently also streaks are found at right angles to the former (they correspond to the teeth of the septal edge), and in many genera, Mussa, the Fungias, Siderastræa, and others, they can be so clearly distinct from each other that one can distinguish individual centres of crystallisation in them, and lines of separations" (*l.c.* p. 236).

Prof. v. Koch then goes on to derive the "porous" and "comb-like" varieties of septa from the simple "plate-shaped" septa, and this practically completes his contribution to the subject of septal structure. Septal varieties and their systematic importance form a large part of my paper presented to the Royal Society in July 1895, and are features shortly indicated in the published "abstract."

With regard to the question of "true" and "false" synapticulæ, Prof. v. Koch does not go beyond the distinction originally drawn by Herr Pratz. But the important fact is that his research *upholds* this distinction even while he declares it to be of small value ; whereas several authors have in recent years declared it quite *untenable*. In this Prof. v. Koch's actual observations again agree with, and were anticipated by, mine ; this is also the case in his statement that both kinds of synapticulæ occur alongside one another in the genus Fungia. A few farther quotations may be compared concerning other parts of the skeleton.

"ABSTRACT," OGILVIE, 1895.

"The microscopic structure of dissepiments and tabulæ is demonstrated by the author to be the same. Both are composed of a series of calcareous growth-lamellæ laid down from one surface only of the aboral body-wall of the polyp. The fibro-crystalline deposit is therefore perpendicular to the plane of contact between polyp and skeleton" (*l.c.* p. 13).

"DAS SKELETT DER STEINKORALLEN," V. KOCH, 1896.

"The fine lines ("Schraffen" denoting the arrangement of the crystals) are always placed nearly perpendicular to the surface of the dissepiment ; there is often in addition a very fine set of lines parallel with the surface, and in this, therefore, the dissepiments closely resemble the stereoplasm of the septum." . . . "A tabula is just the same as the sum of all dissepiments lying in one plane" (*l.c.* p. 260).

"Cases occur in both those families where the only peripheral support is afforded by the epitheca. The author is inclined to think this was the primitive form of the Madreporarian calyx, and to look upon both theca and pseudotheca as later modifications associated with retrogression of the epitheca, greater prominence and rapid growth of the septa, and very often with the processes of vegetative budding (*l.c.* p. 14).

A series of evolutionary changes are enumerated, which appeared within the group of Madreporaria during the course of geologic ages. Among others, the following occur as shortly expressed in the abstract : —"Septa became more prominent and exsert in growth ; their structure became more elaborate, their surfaces fluted and richly granulated, their edges knobbed, toothed, serrated, spined" (*l.c.* p. 16).

"The 'Rugose' epitheca became tardy in growth, and was replaced functionally by a theca or pseudotheca" (*l.c.* p. 16).

"We may accept as a great probability that the primitive skeleton of the Madreporarian corals consisted of a lamellar shedding (Abscheidung) of lime by the ectoderm basis and epitheca, which formed a protective covering round the individual polyps" (*l.c.* p. 272).

"Provided the septa are once present in their due position, it can easily be understood how the varieties of septal structure, briefly described above, may come to originate. In a very low grade they would simply be present as small eminences of the basis and epitheca, and would then eventually grow outwards as longer processes" (*l.c.* p. 273).

"As soon as the wall is once present . . . the epitheca loses its significance as a supporting skeleton, and it continues to exist only as a protective covering outside, which in consequence tends to become less thick." . . . "Especially in colonies the epitheca is completely retrograde round the individual calyxes" (*l.c.* p. 274).

Naturally, Prof. v. Koch's paper of some twenty-five pages treats only a few of the questions examined and discussed in my complete paper of some 275 pages, as it will appear in the *Philosophical Transactions* of the Royal Society. Nevertheless, it is satisfactory that these few points included in Prof. v. Koch's paper should afford strong and independent evidence in favour of results arrived at by me and already published a year ago.

MARIA M. OGILVIE.

British Association.—Toronto Meeting, 1897.

IT is possible a number of the members present at Liverpool were unable to obtain all the information they desired regarding the programme of the Toronto meeting, and others may be glad to avail themselves of an opportunity to obtain information on various subjects connected with the meeting. Kindly grant me the use of your columns to say I shall not return to Canada till probably in February, and that I shall be only too pleased to answer inquiries and give information. My address is "Canaan Lodge, Canaan Lane, Edinburgh." ALAN MACDOUGALL.
Secretary, Local Executive Committee, Toronto Meeting, 1897.
Edinburgh, December 1.

A Case of Abnormal Magnetic Attraction.

LETTER, copy of which is appended, came to me this morning. May be it is of sufficient interest for your readers.

A. G. FROUD.

60, Fenchurch Street E.C., December 4.

S.S. *Coronilla*, Oxelosund, November 30, 1896.

To A. G. Froud, Lieutenant R.N.R., Secretary Shipmasters' Society.

DEAR SIR,—Compasses and their deviations and errors being a matter of importance, you may perhaps be interested in a case of local attraction which came under my notice here.

Whilst approaching here, Hafringe Lighthouse, bearing N.N.W. (c.m.), about six miles distance, our standard compass suddenly started swinging over an arc of sixteen points. On mentioning this to our pilot afterwards, he told me of a nineteen-fathom patch on that bearing and distance which has been found to affect compasses so, and on the latest Swedish charts the bank and its effect are noted. Going out I shall try and pass over it again. Sea was smooth and compass steady at the time.

THOS. ROGERS.

THE NATIVES OF SARAWAK AND BRITISH NORTH BORNEO.[1]

ANTHROPOLOGISTS are again indebted to Mr. Ling Roth for presenting to them, in a convenient form, the results of wide reading and diligent compilation. It is by such well-directed enthusiasm that the labours of the student are materially lightened; for not only has the author, in this instance, marshalled a portentous array of accurately acknowledged quotations, but he has sedulously collected illustrations of objects preserved in numerous museums and private collections, in order to fully illustrate the descriptions that he quotes. It is perfectly evident that this has necessitated an immense amount of painstaking labour, which of itself is sufficient to raise the book from the rank of a mere compilation to that of a work containing original research. It is true that Mr. Ling Roth has borrowed illustrations from other authors; but he has supplied a large number of well-chosen figures, most of which are clever pen-and-ink sketches by Mr. C. Prætorius.

Owing to Mr. Ling Roth's conscientious method of giving verbatim quotations from numerous authors, the book has rather a patchwork appearance which is slightly distracting, and may even be somewhat repellent to certain readers; but this plan is to the advantage of the student, who can thus read the original traveller's observations in his own words. The accounts are at times at variance; but this may be due to the tribes not being always clearly discriminated, and it is well known that local differences are of common occurrence, and there is always the idiosyncrasy of the recorder to be taken into account: when there are many observers, there are likely to be some discrepancies.

Some of the most satisfactory portions of the book are the various essays or detailed descriptions which have in some instances been published before, such, for example, as Archdeacon Perham's memoir on the "Sea Dyak Gods," and the papers by S. B. J. Skertchly, "On Fire-making in North Borneo" and "On some Borneo Traps," or the translation of Dr. Schwaner's ethnographical notes. The author has also contributed others, among which may be mentioned "Alleged Native Writing in Borneo" and "Negritoes in Borneo." The first "Appendix" consists of 160 pages of vocabularies, but, considering the amount of space devoted to lists of words, the chapter dealing with language is meagre; the construction of a language is of more importance than the actual words employed, interesting and suggestive as these often are.

FIG. 1.—Sea-Dyak Women (Sakarang Tribe). The corsets are composed of cane hoops covered with innumerable diminutive brass links.

The Land Dyaks, who occupy the south-west corner of the Raj of Sarawak, are a small, slightly built, untattooed people, with skin and hair similar to that of the Malays; some tribes burn their dead. Their language is quite distinct from that of other groups, and they substitute the letter *r* for *l*. The Sea Dyaks live further to the east; they are more stoutly built, well-proportioned, and tattoo slightly on the arms. They live in long houses along the river-banks, and bury their dead. Both peoples consult birds as omens. The term "Dyak" should be restricted to these two peoples; even now there is some obscurity as to its exact significance. It is probably derived from *dayah*, the generic name for "man"; the Malays, and later the Europeans, learned to call certain peoples Dyaks on account of their general term for men, but the latter never used it as a collective name for themselves. Rajah Sir James Brooke was the first to divide the Dyaks into Land and Sea Dyaks. Some have suggested that the term is derived from a word meaning "inland," that is, the people of the interior.

The Milanaus are a very fair, quiet, sago-cultivating people who inhabit the greater part of the coast of Sarawak east of the land of the Sea Dyaks. Interior to these is the large territory of the allied Kayans. The Kayans are very hospitable, and, like the Hill Dyaks, of the most scrupulous integrity; but the Dyaks are braver, more truthful, less treacherous, and a finer-looking and superior people. Also quite different from, and bigger than the Dyaks, are the Muruts, an inland tribe of very low social scale. The Ukits pass a wandering life among the hills, and do not build houses; they live by hunting, and use the *sumpitan* or blow-pipe. The Muruts extend into the west of British North Borneo; in the centre are the Dusuns, an ill-favoured folk who, according to some travellers, have probably resulted from an infusion of Chinese blood with the aboriginal race of North Borneo.

[1] "The Natives of Sarawak and British North Borneo." By H. Ling Roth; with a preface by Andrew Lang. 2 vols. 8vo, with over 550 illustrations. Pp. xxxii + 464; ccxl + 302. (London: Truslove and Hanson, 1896.)

The eastern part of the territory is inhabited by Sulus. The northern coast contains mongrel populations, the most interesting of whom are the Bajaus, or Sea Gypsies, a curious, wandering, irresponsible sort of race of low culture, who dwell almost entirely in boats. They are supposed to have come from the Straits of Malacca, and they profess Islamism.

The Sea Dyak girls receive their male visitors at night, as privacy in the day is out of the question. About nine or ten at night, the lover quietly opens the door and goes to the mosquito curtains of his beloved, gently awakens her, and they sit conversing together. Of course, if this nocturnal visit is frequently repeated, the parents do not fail to discover it, although it is a point of honour to take no notice of him; if they approve, matters take their course, but if not, they use their influence with their daughter to say to him, "Be good enough to blow up the fire," the usual form of dismissal. These nocturnal visits but seldom result in immorality. The natives of Borneo appear to be a very moral people, on the whole, both before and after marriage. A good deal of freedom is permitted among some tribes to the lover, as a precaution against a sterile marriage, but marriage almost invariably follows pregnancy. Often a girl will commit suicide rather than face the disgrace of an unacknowledged child. Usually the bridegroom lives with or near his father-in-law (whom he often treats with more respect than his own father), and works for his benefit. Polygamy is rare. Divorce is very frequent, and may be obtained for a large number of causes or pretexts—bad temper, gossiping, laziness, unfaithfulness, any of which are deemed sufficient reasons for divorce without incurring a fine, as are also troublesome dreams and various omens; but, on the whole, the marital relations are satisfactory. The couvade is in force among both the Land and Sea Dyaks. At a birth the husband is confined to his house for eight days, and may eat only rice and salt, and for one month he ought not to go out at night.

The Kanowits follow the Milanau custom of sending much of a dead man's property adrift in a frail canoe on the river; they talk of all his property, but this is exaggeration. Mr. St. John, after describing the display of a dead chief's worldly possessions, goes on to say: "As I expected these valuables were not sent adrift, but merely a few old things, that even sacrilegious strangers would scarcely think worth plundering." Burning of the dead is confined to the Land Dyaks; the Sea Dyaks either bury theirs, or place the coffin in a miniature house built on piles eight or ten feet high; the latter is also a Kayan custom. A very wide-spread custom of the natives of Borneo is that of depositing the relics of their dead in a jar. In many places slaves or others are sacrificed at the funeral of an important man, in order to attend him in the future life. Some tribes have the cheerful practice of dancing round a tied-up slave, and as each man slightly wounds him they send messages to their deceased relatives, but the wounds are sufficiently numerous to cause his death. One tribe now substitutes a pig for a man.

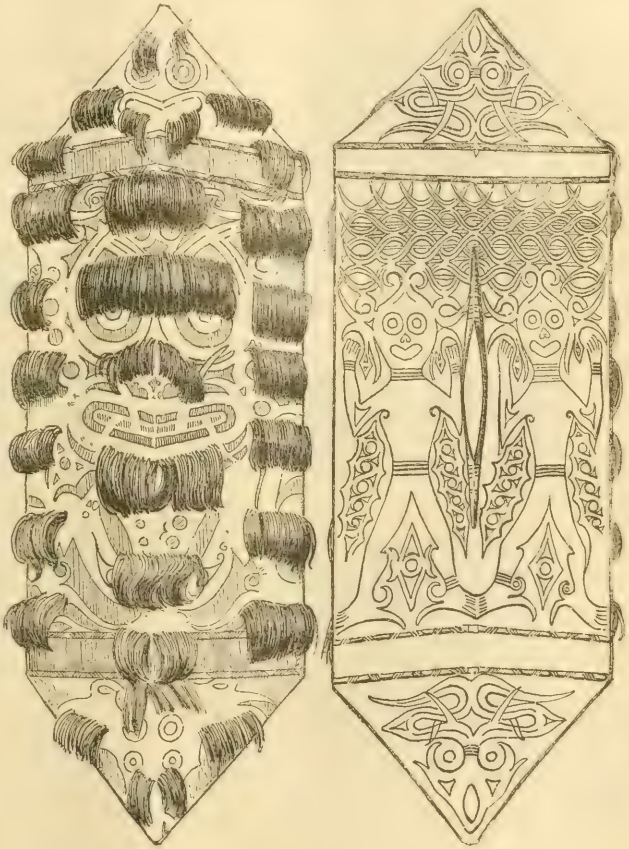

FIG. 2.—Kenniah Shield from Sarawak (length 48½ inches), Edinburgh Museum.

There are two explanations of the notorious custom of head-hunting, which is by no means confined to the Dyaks. There can be little doubt that one of the chief incentives to getting heads is the desire to please the women. Among some tribes it is said to be indispensably necessary a young man should procure a skull before he gets married, and the possession of a head decapitated by himself seems a pretty general method of a young man ingratiating himself with the maiden of his choice. Some tribes believe that the persons whose heads they take

will become their slaves in the next world; and Sir Hugh Low states that among the Kayans, before a person can be buried, a head must be obtained. Several travellers are of opinion that the passion for head-hunting, which now characterises these people, was not formerly so deeply rooted in their characters as it is at present, although to a limited extent it is probably an ancient custom. The second reason is a fairly satisfactory explanation of the origin of the custom, and the first for its extension, as the fact of a young man being sufficiently brave and energetic to go head-hunting would promise well for his ability to keep a wife.

The religious observances of the Land Dyaks consist of setting aside of a portion of fowl and pig-meat for the deity; the propitiation by small offerings of rice, &c., of *Antus*, or spirits (of these there are two kinds, demons and ghosts of departed men); the *pamali*, or taboo; obedience to the medicine women, and belief in their pretensions; dancing; the use of omens from the notes of various birds.

On reading this book, one is constantly reminded how much more information must be collected before a complete record of the people can be gained; as Mr. Lang points out in his preface, "the writers quoted by Mr. Ling Roth were not, or not usually, anthropologists who knew what to look for"; on the other hand, as Mr. Lang says, "inquirers who know what to look for, are only too likely to find it, whether it is there or not. This is the dilemma of anthropological evidence." It is to be hoped that the publication of this work will result in renewed and definitely directed observations on the spot.

One important line of inquiry, the significance of the decorative art, is totally unrepresented in the materials at Mr. Ling Roth's disposal. That this is a promising field for research is evidenced by a recent paper by Dr. W. Hein, "Zur Entwicklungsgeschichte des Ornaments bei den Dajaks" (*Ann. k. k. Naturhist. Hofmuseums*, Wien, Band x. Heft 2). This study deals only with anthropomorphic designs, but it is probable that the motives are much more varied. The characteristic and very effective designs on Bornean shields are also mostly derived from the human form.

To those who are conversant with the evolution of savage decorative art, it is evident that such patterns as those on Kanowit baskets have a significance which is at present unsuspected. As an example of the difficulty a student at home finds in endeavouring to interpret the significance of a native pattern, we have only to look at the design to the left in the illustration on p. 38 of Mr. Ling Roth's book, which, without a clue, could never have been imagined to indicate a cloudy sunset.

Sufficient has been said to show that this book is a valuable storehouse of information, and it also reflects great credit on the publishers for the artistic manner in which it has been produced. An idea of the character of the illustrations may be gained from the three which accompany this notice. ALFRED C. HADDON.

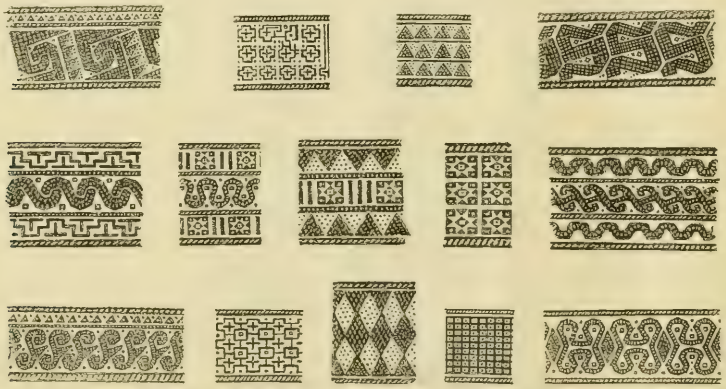

FIG. 3.—Patterns on Kanowit Baskets in the Brooke-Low Collection.

THE ALLOYS OF COPPER AND ZINC.

ON account of their great industrial importance, the alloys of copper and zinc have at various times been studied by many observers. Mallet, Matthiessen, Riche, Thurston, and a host of others have made contributions of varying importance to the literature of the subject; but so difficult is it to eliminate the accidental differences in the physical conditions that Prof. Thurston announced, as late as the year 1893, that the curves representing the variations in the properties of brasses were so irregular that the effects of composition only (irrespective of other conditions) must remain unknown until further researches should be made. To the task thus indicated M. G. Charpy has addressed himself, and has succeeded in notably advancing the knowledge on the subject.[1] He did not confine himself to the mechanical properties, but has also made a careful investigation of the micrographic properties of a number of alloys, a branch of the subject which had already been attacked by Guillemin and by Behrens in 1894.

Among the results of the mechanical tests, none are more interesting than the determination of the effects of variation of the temperature used in annealing pieces of brass which had previously been hardened by repeated rolling. M. Charpy finds that, if the maximum temperature of annealing is maintained for some time, the mechanical and micrographical properties of test pieces of similar composition depend only on that temperature. The tensile strength of metallic copper, in kilogrammes per square millimetre, when annealed at different temperatures, is shown in Fig. 1, the shape of the curve

1 "Recherches sur les Alliages de Cuivre et de Zinc," by M. G. Charpy (*Bull. de Soc. d'Encouragement*, 5th series, vol. i. p. 180, February 1896).

A B C D being similar in the case of all the brasses. It may be seen that reheating has no effect on the tensile strength of copper unless the temperature exceeds 280°, when there is a progressive lowering of the tensile strength until the temperature reaches 420°. Above that point a further increase of temperature has no effect on the metal, the annealing being complete. Finally, when the temperature is so high that the copper is "burnt," the tensile strength again falls off rapidly.

It is remarkable, however, that the more thoroughly the test piece is hardened, and consequently the higher its initial tensile strength, the lower is the temperature (in the above instance, 280°) at which the annealing effect becomes sensible. M. Charpy suggests, therefore, that in pure, completely hardened copper or brass, any increase in temperature, above that at which the hardening was effected, would cause a reduction in the tensile strength, and that the broken curve C B A would then be a straight line, C B E. It would thus be predicted, as may be seen by a glance at the diagram, that the tensile strength of completely hardened pure copper would be about 52 kilogrammes per square millimetre, and, as a matter of fact, A. Le Chatelier raised the tensile strength

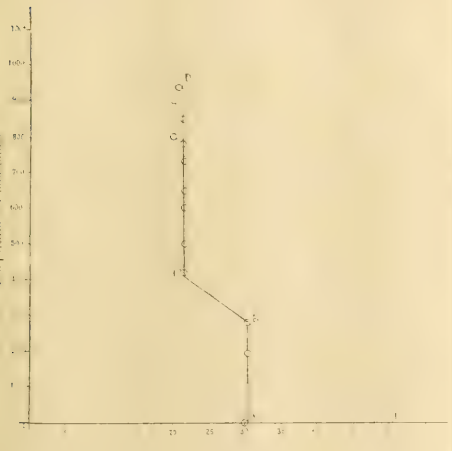

FIG. 1.—Variations in the tensile strength of metallic copper.

of copper to 51 kilogrammes by successive wire-drawings. In spite of this close agreement, the inference must be accepted with some caution, for apparently there were no experiments made on copper annealed at temperatures between 280° and 420°. Nevertheless the approximate correctness of the general direction of the line B C is attested by a number of results obtained on the analogous parts of the curves obtained by studying the brasses, whence, for example, it may be deduced that the maximum tensile strength of the alloy containing 30·2 per cent. of zinc should be about 70 kilogrammes per square millimetre, or 44 tons per square inch.

In tests made on completely annealed bars, in which M. Charpy believes that all accidental differences in the physical conditions are eliminated, he finds that the tensile strength increases with the percentage of zinc, passes through a maximum when the alloy contains about 45 per cent. of zinc, and then decreases rapidly. The elongation increases similarly with the percentage of zinc, but passes through a maximum when the alloy contains 30 per cent. of zinc, and then decreases rapidly. It follows that there is no advantage in using for industrial purposes alloys containing less than 30 per cent. of zinc, as they are more costly, and possess both less resistance and less malleability than those richer in zinc. On the other hand, if there is more than 43 per cent. of zinc present, the alloys are brittle, and should not be employed, so that only those with from 30 to 43 per cent. of zinc can be recommended for use.

In the micrographical researches, in which enlargements of 30 diameters with obliquely falling light were studied,

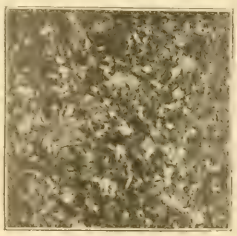

FIG. 2.—Alloy containing copper 80 per cent., zinc 20 per cent., annealed at 700°.

appearances were noted by M. Charpy corresponding to many of the results of the mechanical tests. Thus, for example, on hardening alloys containing from 0 to 35 per cent. of zinc by passing them through the rolls, the crystals are gradually deformed and disappear, a homogeneous granulated surface being obtained. When the hardened alloys are annealed, the crystals are reformed, their size depending on the maximum temperature attained, and not on the length of time during which they were subjected to it. No striking change is produced by reheating to temperatures below that at which

FIG. 3.—The same annealed at 900°, showing increase in the size of the crystals.

complete annealing is effected, but above that temperature the alloys become completely crystalline, showing no amorphous magma, and the crystals grow larger and larger as the temperature is raised and the tensile strength falls off. Thus Fig. 2 shows an alloy containing 20 per cent. of zinc which has been hardened and annealed at 700°, and Fig. 3 shows the same alloy annealed at 900°. The crystals are octahedra with numerous macles, and are obviously larger in the latter case than in Fig. 2.

When the reheating is carried to a very high tem-

perature, near the melting point of the alloy, so that it is "burnt," a number of blowholes, looking like bubbles of gas, make their appearance (see Fig. 4, which represents commercial brass, containing 30 per cent. of zinc, after it has been annealed at 820°). As the temperature rises, these blowholes increase in number, and at the same time fissures develop round the crystals and eventually form a complete network. It appears that an alloy, not easily fusible, forms round the crystals, and, becoming liquefied, rounds off and corrodes them, thus giving the appearance of fissures. These effects are more readily produced if traces of lead and tin are present, as is usually the case in commercial brass, and the network round the crystals doubtless contains these metals. Under these circumstances the test pieces are of little tensile strength, and are not malleable.

M. Charpy prepares the alloys for examination with the microscope by etching the polished surface by electrolytic attack He points out that the fracture is useless as a guide to the mechanical properties of any metal or alloy. It has usually been supposed, owing to the appearance of the fracture, that a highly crystalline metal is necessarily fragile ; but this is far from being the case. Brass may be mainly composed of crystals as much as one millimetre in diameter without any interstitial matter, and yet may have an elongation of 60

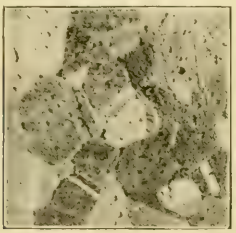

FIG. 4.—Commercial brass, containing traces of lead and tin, "burnt" by being annealed at 820°.

per cent. The only deduction that can be drawn from the appearance of the fracture is that if the crystalline structure is revealed in this way, the metal is brittle and of little tensile strength.

The microscopic structure revealed by etching polished surfaces enables the alloys of copper and zinc to be divided into three classes—those containing less than 35 per cent. of zinc, those containing from 35 to 45 per cent. of zinc, and those containing more than 45 per cent. of zinc. It enables the observer to determine whether the metal has been cast, and, according to the size of the grain, whether the casting has been made at a high or a low temperature, and what is the nature of the mould. It shows the effects of hardening, of annealing at various temperatures, and, lastly, shows whether or not the metal has been burnt.

M. Charpy infers, from the identical appearance of the alloys containing less than 35 per cent. of zinc, that these all consist of isomorphous mixtures of copper with the compound Cu_2Zn, which contains about 66 per cent. of copper. He also confirms the existence of the compound $CuZn_2$ containing 67·2 per cent. of zinc, which forms a perfectly homogeneous alloy under all conditions, and finds that if more zinc than this is present, it remains in the free state soluble in potash. On the other hand, M. Charpy expresses no opinion as to the form in which the metals are present in the alloys containing more than 34 and less than 67 per cent. of zinc. T. K. ROSE.

DR. BENJAMIN APTHORP GOULD.

ANOTHER busy life, devoted to the advancement of astronomy, is ended by the death of Dr. B. A. Gould. Practically, half a century has passed since his name came prominently before the public, in connection with the establishment of an astronomical journal in America, and throughout this period he has maintained a foremost place in the ranks of American astronomers by the unwearying energy he has exhibited, and the mass of work he has accomplished. For many years he was attached to the United States Coast Survey, where, under Superintendents Bache and Peirce, he did good service in the determination of longitudes at stations along the Atlantic seaboard, from New Orleans to the extreme north-eastern boundary of the United States. In those early days the employment of the method of telegraphic signals had not long been in use in America, and was scarcely known in Europe, and its subsequent development for longitude investigations owes much to the energy that Dr. Gould brought to bear upon problems of this character. When the Atlantic cable was successfully laid, he perceived the advantages it offered to connect the American with the European longitudes, and thus to practically reduce the two independent series of determinations into one complete system.

It was while engaged on the staff of the Coast Survey, and anxious in every way to promote its interests, that he became unfortunately embroiled with the Trustees of the Dudley Observatory. It is not necessary to make any further allusion to this unhappy affair, beyond expressing our belief that Dr. Gould was a much-injured and much-persecuted man. Conducting, as he was at the time, an American journal of high repute, and fully employed on the affairs of the Coast Survey, he probably was ill-advised to attempt to direct the Dudley Observatory, by giving to the institution the leisure that his other occupations permitted. But if he erred in judgment he suffered severely. That there is abundant evidence to show ; but that his reputation rose above the attacks of his persecutors, is a matter for congratulation. The Dudley fiasco came about in 1859, and in the next year Abraham Lincoln was elected to the Presidency, the war of Secession was imminent, and with the troubles that supervened, the *Astronomical Journal* was suspended. Not that Dr. Gould's industry was less. A glance at the Royal Society's catalogue of papers shows a long list attached to his name, and some of them, such as the reduction of D'Agelet's observation, involved considerable labour. It is possible here, however, only to refer to his best-known work, the successful establishment of an observatory at Cordova, and the great amount of work therein accomplished. The observatory itself is the outcome of a private expedition that Dr. Gould planned to the Argentine Republic, in order to extend to the southern hemisphere the system of zone observations that Bessel and Argelander had applied to the north. This private expedition was welcomed and adopted by the Argentine nation, and led to the foundation of that national observatory under whose auspices those valuable and extensive catalogues have been published, and whose preparation kept Dr. Gould at Cordova some fourteen years. While waiting for the full instrumental equipment of the observatory, Dr. Gould and his assistants occupied themselves with the preparation of charts of the southern hemisphere, giving the position of those stars that could be seen with the naked eye, and assigning to them magnitudes, which practically extended Argelander's scale to the whole heavens. For this work he was awarded the Gold Medal of the Royal Astronomical Society ; he had been elected a foreign associate in 1855.

Dr. Gould on leaving South America returned to Boston. Here, in 1886, after an interruption of twenty-

five years, the *Astronomical Journal* again made its appearance under his editorship, and seems likely to have a long and prosperous career.

Although Dr. Gould's reputation as an astronomer will probably rest on the manner in which he carried to a successful issue long, and even wearisome, undertakings, involving continual repetitions of the same processes (witness the Cordova Zone Catalogue and the long series of longitude determinations), it must be admitted that he was keen to recognise the merits of new developments. He must be regarded as one of the first, if not *the* first, to foresee the practical advantages of the application of photography to the accurate determination of star places. So far back as 1866, he had co-operated with Mr. Rutherfurd in photographing the Pleiades, and had deduced the positions of some fifty stars in this group, clearly demonstrating the smallness of the average error of measurement, and the possibility of using those measurements in cosmical inquiries. Later he measured the relative coordinates of the stars in the Præsepe cluster, and the plan of operations proposed for the conduct of the Cordova observatory orginally contemplated the employment of photographic apparatus. The disappointment that Dr. Gould suffered on finding the object-glass broken on its arrival at Cordova is a matter of history, and his heroic attempts to repair the mischief show how fully he appreciated this line of investigation and his eagerness to promote it. W. E. P.

NOTES.

WE referred last week to a very unworthy insinuation, contained in a leading article in the *Times*, that Lord Rayleigh had retired from the Council of the Royal Society owing to a want of sympathy with, or a want of respect for, his colleagues. Lord Rayleigh has since sent the following letter to the *Times*.

"Sir,—In your issue of Tuesday, after some too flattering remarks regarding my tenure of office, you say that I have taken the unusual step of declining to sit on the Council, and that no one who knows the play of forces within the Society can doubt that my refusal is significant. There seems to be here a suggestion that my retirement is due to a difference with my colleagues—colleagues with whom I have worked for eleven years in complete harmony, and for whom I retain the highest regard.

Permit me to say that my retirement is significant only of a desire to escape engagements involving journeys to London, and of a possibly mistaken impression that the position of an ex-Secretary as an unofficial member of Council would be a little anomalous. "I am, Sir, yours faithfully,

"Dublin, December 2." "RAYLEIGH.

THE Davy-Faraday Research Laboratory of the Royal Institution, founded by Dr. Ludwig Mond, F.R.S., will be opened by the Prince of Wales on Tuesday afternoon, December 22.

THE first instalment of the Austin Corbin herd of buffalo, twenty-five in number, has just been removed from the Corbin Estate, in New Hampshire, to Van Cortlandt Park in New York City.

THE eleventh German Geographical Congress will be held at Jena on April 21, 22, and 23. The papers and discussions will principally refer to polar investigations, physical geography, biological geography, the topography and natural history of Thuringia, and the teaching of geography in schools.

THE death is announced of Dr. Karl Sebastian Cornelius, the author of many works on physics and physical geography, and privat-docent, with the title of Professor, in the University of Halle. We also notice the death of the zoologist, Dr. Fritz Westhoff, of the Königl. Akademie at Münster.

MR. P. F. COOK sailed for Hamburg a few days ago in the interests of the American Colonisation Society and of the Smithsonian Institution. He will remain a month at the Hague, studying myriapods and insects, and will then proceed to Siberia for a residence of several months, to conduct investigations of scientific and economic matters.

THE Liverpool Chamber of Commerce has unanimously adopted a resolution in favour of the adoption of the metric system of weights and measures, and urging that at the earliest possible moment consistent with the public convenience a Bill should be brought in to make the system compulsory.

DR. BERNARD DYER has been elected President of the Society of Public Analysts for the year 1897. The newly-nominated Hon. Secretaries are Mr. E. J. Bevan and Mr. Charles E. Cassal.

WITH reference to our note of November 19 (p. 58), on the "Welby Prize," we are requested to announce that, in consequence of unforeseen delays, it is found desirable to extend the time allowed to competitors till January 1, 1898, and that Prof. Émile Boirac, Paris, becomes the French member of the Committee of Award.

AFTER an absence of three years, the expedition under Lieut. Hourst has safely returned to Europe from the Niger. The party ascended the Senegal River, and then carried the section of an aluminium boat overland to the upper part of the Niger. On reaching this river the pieces of the boat were put together, and two native boats purchased. In these the expedition sailed down the Niger to Timbuctoo, where a stay of ten months was made. The voyage from Timbuctoo to Lokoja, at the confluence of the Niger and Benue, seems to have been arduous, but from that point the expedition was towed by a launch belonging to the Royal Niger Company to the coast at Wari. How much fresh topographical information Lieut. Hourst's party has obtained is not yet stated; this will depend on the highest point reached on the Niger. Reuter's message states that the expedition "first met the river Niger at Kayes"; but that town is on the Senegal River. There can be no doubt, however, that much valuable scientific information was obtained, for the expedition travelled slowly, and was admirably equipped. One novelty was the use of a phonograph for reporting the native war songs. The expedition kept peace with the natives throughout the journey, in which it differs greatly from some of those previously conducted by French explorers in that region.

THE success which has attended the installation of a meteorological observatory on the summit of Mont Blanc has (says the *Daily Chronicle*) stimulated Italian men of science to crown Monte Rosa with a similar edifice. Queen Margherita, herself an expert mountaineer, supports the project by a donation of 160*l.*, the Duke of the Abruzzi gives 200*l.*, and the Italian Alpine Club, the Ministers in their private capacity, and the physical faculty of the University of Turin figure among its chief contributors. It is intended to utilise the hut on the Gniffetti peak, built three years ago as a shelter for climbers. Situated at a height of about 14,000 feet above sea-level, the observatory will, as regards elevation, rank fourth among the twenty-seven mountain observatories of the world, being surpassed in altitude only by those of Arequipa, Mont Blanc, and Pike's Peak.

IN 1897, for the first time since the British Medical Association came into existence, the annual meeting will be held outside the British Isles. In order to induce as many members of the Association as possible to decide to go to Canada next year, the *British Medical Journal* prints an illustrated article in the current number, showing the extensive preparations already co-

menced at Montreal, and giving valuable details as to ways of reaching the Dominion, and the cost of the journey. It may be remembered that the Association will meet on Tuesday, August 31, and three following days. This date has been decided upon for several reasons, the most important being that the British Association meets in Toronto from August 18 to 27. It will thus be possible for those who can spare the time to attend both meetings.

IT is proposed to hold an international electrical exhibition at Turin in 1898. The Executive Committee and the Special Commission invite exhibits from all parts of the world, and the exhibition will comprise the following classes: (1) Apparatus for teaching electro-technics; (2) materials for the conduction of electricity; (3) instruments for electric and magnetic measurements; (4) telegraphs and telephones; (5) signalling apparatus and safety appliances on railways, lighting and heating of carriages; (6) dynamos and motors; (7) mechanical appliances and electric traction; (8) electric lighting; (9) electro-chemistry and electro-metallurgy; (10) miscellaneous; (11) apparatus of historic interest. Signor Galileo Ferraris has been appointed President of the Commission.

DURING the past week this country has been visited with very severe gales, the greatest violence of which seems to have been felt on the South Coast. The reports issued by the Meteorological Office show that on the morning of the 4th instant the centre of a very deep depression suddenly appeared near the mouth of the English Channel, and advanced eastwards to the Channel Islands, where the barometer fell as low as 28·32 inches. During the night the storm changed its direction and moved northwards over England, while the wind increased to a whole gale from the southward, accompanied with heavy rain, and very high seas. In the neighbourhood of London the maximum wind force was registered at about 1 a.m. on the 5th, or between two and three hours after the time of the destruction of the Chain Pier at Brighton. The pressure recorded by the anemometer at the Royal Observatory was 18 lbs. on the square foot, which is equivalent to a velocity of about seventy-eight miles in the hour.

THE death of Prof. Emil von Wolff, in his seventy-eighth year, has just taken place at Stuttgart. The *Times* gives the following particulars of his career: "Born at Flensburg in 1818, he took his doctor's degree in the University of Berlin in 1843, and in the same year he was appointed assistant in the chemical laboratory in the University of Halle. Four years later he became instructor in chemistry at the agricultural institute at Brösa, near Bautzen. After passing some years at Möckern, near Leipzig, at the first agricultural experiment station ever founded in Germany, he was in 1854 called to the chair of Agricultural Chemistry at the Royal Agricultural College, Hohenheim, Wurtemberg. This post he retained for the rest of his life, so that he occupied the chair for a period of forty-two years. In 1868 he published a work dealing with practical systems of manuring, and six years later appeared the work which has made his name known throughout the world; this was his 'Landwirtschaftliche Fütterungslehre,' in which he dealt with farm foods and the rational feeding of farm animals. Since then the work has run through half-a-dozen editions, and has been translated into various languages, though long before any complete translation was attempted his tables of analyses of foods had been adapted to and incorporated with many volumes published in England, France, and the United States. As an authority on animal nutrition and the composition of foods Wolff stood pre-eminent, and all of the methods of the so-called rational feeding of live stock trace their origin to him and to the enthusiasm of the many students whom he trained during the last half-century."

A COMPETITION between heavy vehicles propelled by automatic traction is being organised by the Automobile Club of Paris; and in order that the makers of all kinds of cars, waggons, and similar vehicles should have plenty of time to prepare for the contest, which is open to all the world, the official programme has already been issued. The contest is to be for vehicles transporting passengers and goods on the high roads not in direct communication with railways, and it is to be held over roads in the vicinity of Paris on July 1, and five following days. A committee will be appointed to see how the competing vehicles work, whether they stop readily on the inclines, what speed they attain up and down hill, and, in a word, to judge how far they are likely to be of practical use. The prizes will be awarded with special reference to these qualifications. In order further to encourage makers of motors to compete, the Automobile Club will prepare an official report of the trials, and send it to all the civil engineers, industrial companies, and mayors in France. Entries may be made, and full particulars obtained from the Secretary of the Automobile Club, Place de l'Opéra, Paris.

AT the Royal Institution, on Monday, the special thanks of the members were returned to the Duke of Northumberland, K.G., President of the Institution, for a donation of 200*l.* to the fund for the promotion of experimental research at low temperatures; to Colonel Coleridge Grove for a bust of his father, the late Sir William Grove; and also to Prof. Dewar, for a marble pedestal for the bust. The following are among the lecture arrangements at the Institution before Easter:—Prof. S. P. Thompson, six lectures (adapted to a juvenile auditory) on light, visible and invisible; Prof. Augustus D. Waller, twelve lectures on animal electricity; Prof. Henry A. Miers, three lectures on some secrets of crystals; Dr. J. W. Gregory, three lectures on the problems of Arctic geology; Prof. Percy Gardner, three lectures on Greek history and extant monuments; Prof. W. Boyd Dawkins, three lectures on the relation of geology to history; Mr. Walter Frewen Lord, three lectures on the growth of the Mediterranean route to the East; and the Right Hon. Lord Rayleigh, six lectures on electricity and electrical vibrations. The Friday evening meetings will begin on January 22, when a discourse will be given by Prof. Dewar; succeeding discourses will probably be given by the Right Rev. the Lord Bishop of London, Prof. Jagadis Chunder Bose, Prof. John Milne, Dr. G. Johnstone Stoney, Lieut.-Colonel C. R. Conder, R.E., Mr. Shelford Bidwell, Prof. Arthur Smithells, Sir Edward Maunde Thompson, Sir William Turner, Mr. Charles T. Heycock, and the Right Hon. Lord Rayleigh.

SOME interesting information regarding the effects of inoculation for cholera is to be found, according to the *Pioneer Mail*, in the report on the railway reconnaissance from Assam to Burmah *viâ* the Hukong valley. Mr. Way, the engineer-in-chief, had to engage coolie transport, and 357 Khasias were collected at Margherita. Cholera was raging in the neighbourhood at the time, and, in spite of all precautions, the coolies were attacked. Fortunately, Surgeon-Captain Hare was at Dibrugarh, engaged in the special duty of inoculating labourers on the tea gardens, a work which had been begun by Dr. Haffkine some time before. He willingly agreed to deal with the Khasias, and the majority of them submitted to inoculation. The effect was very marked; the deaths among the inoculated were only 2·55 per cent., while among the uninoculated they came to nearly 19 per cent. The disease made such ravages among the latter that the coolies themselves became thoroughly convinced of the efficacy of inoculation, and finally all agreed to undergo the treatment. From that time onward no fresh cases of cholera occurred. Dr. Hare states that the 52 men first dealt with

formed a separate group messing together in the same sheds. Of these, 30 were inoculated and 16 left; of the 16 uninoculated, 11 developed cholera and died; among the 36 there was only one case, but this terminated fatally. There seems to be no room for doubt that if all the coolies had been inoculated at the outset the disease would have ceased in a few days.

THE Maryland Geological Survey, in an endeavour to make its work fundamental, and at the same time of the greatest value to the material interests of the State, has taken up, in its preliminary investigations, a thorough study of the magnetic conditions affecting that portion of the earth's crust within the borders of Maryland. In addition to the importance of this work upon the future observations and determinations of the great rock-masses contained within the State, these investigations will be of immediate practical benefit to all land surveyors, and from that standpoint alone justify the undertaking. We learn from an advance sheet from *Terrestrial Magnetism* that the investigations are being conducted by Dr. L. A. Bauer, under the direction of the State Geologist, Prof. W. Bullock Clark. The Survey will ultimately average one station to about 140 square miles, thus equalling in detail that of Rücker and Thorpe in the British Isles. There is probably no State in America that presents, within so small an area, such a variety of geological formations as Maryland. It is then peculiarly fortunate that a detailed magnetic survey has been undertaken in this State, and simultaneously and in connection with the Geological Survey. It is hoped that other States will soon follow the example set by Maryland.

AT a recent meeting of the Otago Institute, Mr. G. M. Thomson exhibited some interesting fossil remains obtained from a mining claim at St. Bathans. The fossils occurred in a bed of hard clay which was overlaid by 30 feet or 40 feet of lacustrine (marine?) clays. They consist of leaves and fruit capsules of a species of Hakea. The genus Hakea belongs to the order Proteaceæ, and is at present confined to Australia, where about 100 species are known. Of these sixty-five have only been found hitherto in West Australia. The occurrence of the genus in New Zealand in Tertiary times is of great interest in its bearing on questions of geographical distribution.

AMONGST the things recently exhibited at the opening meeting of the Geologists' Association and at the "at home" of the Geological Society, one that deserves attention was shown by the Geological Photographs Committee of the British Association. Several portfolios were exhibited which contained the prints recently acquired by that body, among them being a fine set of views of the Yorkshire Coast taken by Mr. Bingley, a large series of small photographs taken during the recent re-examination of Charnwood Forest by the Geological Survey, and some most useful prints showing the chalk of Beer and the landslips of that neighbourhood, taken several years ago by Sir Henry T. Wood. The whole collection, now numbering about 1400 photographs, is lodged in the library of the Jermyn Street Museum, where it is borne company by the Survey collection of prints taken and acquired by the officers of the Geological Survey, the two collections supplementing one another. Although so much has been done, the labours of the Committee are by no means over, and many parts of Britain still need to be surveyed by the camera. Many local bodies have given ready aid to the work, and they must still be looked to to watch for phenomena which ought to be registered, and to help in keeping the collection up to date. It is hoped that this may come to be a recognised part of the work of local societies, and no pains are being spared to enlist the services of new societies, and to encourage those which have begun, to continue in their good work. Among the districts scarcely, if at all, represented at present in the collection are the following:—Bedford, Bucks, Berks, Cambridge, Cumberland, Essex, Gloucester, Hants, Hereford, Herts, Huntingdon, Lincoln, Middlesex, Monmouth, Norfolk, Northants, Nottingham, Oxford, Rutland, Stafford, Suffolk, Surrey, Sussex, Warwick, Westmoreland, Wiltshire, Worcester, South and Central Wales, Scotland, except parts of the Highlands and of the Central Valley, S.E., S.W., W., and Central Ireland. It is true that some of these districts do not lend themselves so well as others to this method of illustration, but what work there is should be done without delay. There will thus be got together a set of illustrations which will be a most valuable addition to published maps, sections, papers, and memoirs, and one which will in many respects remedy the deficiencies and supply the omissions of the methods of illustration usually employed.

PROF. E. VILLARI describes (*Atti dei Lincei*, v. 8) some fresh experiments relating to the property possessed by Röntgen rays of inducing in gases the power of discharging electrified bodies. This power is found to persist for a certain time after the rays have ceased, and it is not altogether destroyed, although considerably reduced, by causing the gases to flow through a tube several metres long. Sparks from an induction coil, whether reinforced by a condenser or not, are found to impart the same discharging power to gases, and their efficacy in either case increases at first with the length of the spark; but after a certain length of spark has been exceeded, the efficacy without the condenser decreases to zero. Another series of experiments on the electrostatic dispersion of Röntgen rays is described by Dr. Uno Panichi (*Rivista Scientifico-Industriale*), who examines the question of whether Röntgen rays are emitted from a Crookes' tube after the discharge within the tube has ceased. Dr. Panichi finds that within 1/50 of a second from the termination of the discharge, the Crookes' tube has no effect whatever on an electroscope, so that any after-effects which may be observed in other experiments must be due to the aforementioned modifications in the air which has been traversed by the rays.

THE January number of *Science Progress*, which now appears quarterly and in an enlarged form, will contain important and interesting articles on "Liquid Crystals," by Prof. H. A. Miers, F.R.S., Professor of Mineralogy in the University of Oxford; on "Selection in Man," by Dr. John Beddoe, F.R.S.; on "The Glossopteris Flora," by A. C. Seward, Lecturer on Botany in the University of Cambridge; on "Condensation and Critical Phenomena," by Dr. E. T. Kuenen.

A COMPLETE list of the scientific writings of the late Prof. Adolfo Bartoli has been compiled by Dr. Carlo del Lungo, and is published in the *Rivista Scientifico-Industriale* for August–October 1896.

FROM Profs. Elster and Geitel, we have received a copy of their important paper, published in the current volume of *Wiedemann's Annalen* (pp. 487–496), on the photo-electric after-effects of kathodic rays.

THE snakes found within fifty miles of New York City are enumerated by Mr. R. L. Ditmars, with brief descriptions of the species, and notes on their local distribution and habits, in an "Abstract" (No. 8) of the *Proceedings* of the Linnean Society of New York.

THE Deutsche Seewarte has issued the seventh volume of *Ueberseeische meteorologische Beobachtungen*, containing actual readings and monthly results of various stations in distant parts of the globe. The observations in Labrador are especially interesting to students of weather sequences which may affect this country, as many areas of low barometric pressure between Canada and the North Atlantic Ocean take their course over that peninsula. In addition to four stations in Labrador, the present part contains observations from Walfish Bay, Samoa,

and German East Africa—altogether twelve stations. The observations are made with trustworthy instruments, and by competent observers, and form a valuable contribution to meteorological knowledge.

PROF. A. KLOSSOVSKY, Director of the Meteorological Service of the South-east of Russia, has sent us a *résumé* of work done during the last ten years. The headquarters of the Service is established at the magnetical and meteorological observatory of Odessa; this institution was founded by the Minister of Public Instruction, and has an annual allowance from the local municipal authorities. The main credit for the establishment of the system is due to Prof. Klossovsky, who for some years maintained it by his own exertions, being of the opinion that in so large a country as Russia, investigations of this nature, intended chiefly for the benefit of agriculture, cannot be managed and controlled by the central office at St. Petersburg. At the present time Prof. Klossovsky has enlisted the services of nearly 1000 observers, who deal more especially with rainfall, hail and thunderstorms. In addition to the yearly volumes of results, several investigations of considerable importance have been published.

PHYSICAL chemists have been anxiously awaiting the publication of the sections on chemical affinity required to complete the second enlarged edition of Dr. Ostwald's indispensable "Lehrbuch der allgemeinen Chemie" (Wilhelm Engelmann, Leipzig). This branch of the subject has been left for the second part of the second volume; and the first instalment of that part, dealing almost entirely with the history of chemical affinity, has just been published. It is expected that the treatment of the subject will occupy four or five instalments of about the same size as the present one, which runs into 208 pages, and all of them will be published in the course of next year. We propose to await the completion of the work before reviewing it, and at present content ourselves with announcing the appearance of one instalment.

THE December number of the *Geographical Journal* is full of interesting papers and notes. Mr. Montefiore Brice's account of the work of the Jackson-Harmsworth polar expedition, read before the Royal Geographical Society on November 10, is printed in full with illustrations, and appended to it is a report by Mr. Harry Fisher, the botanist to the expedition, on the flora of the Franz Josef Archipelago. Prince Henri d'Orleans describes his journey from Tonkin by Tali-fu to Assam. The eruption of Ambrym Island, New Hebrides, South-west Pacific, in 1894, is described, and illustrated from photographs, by Commander H. E. Purey-Cust, R.N. Mr. John L. Myres' paper, in which he gives an account of an attempt to reconstruct from the text the maps used by Herodotus, is very suggestive. Among the notes we observe the announcement that the Council of the Society not only intends to present Dr. Nansen with a special gold medal for his recent Arctic expedition, but also to award silver replicas of the medal to Captain Sverdrup, Lieut. Scott Hansen, Lieut. Johannesen, and Dr. Blessing, and replicas in bronze to the other members of the expedition.

THE effect of pressure on the velocity with which acids bring about the inversion of cane-sugar has recently been the subject of several investigations. It is well known that, at atmospheric pressure, the velocity of inversion is very nearly proportional to the degree of electrolytic dissociation of the acid used. Further, the degree of dissociation of acids increases, in general, with increasing pressure; it might thus be supposed that the rate of inversion of sugar under the influence of acids would do so also. Röntgen found that with strong, *i.e.* almost completely dissociated acids, the contrary was the case. Rothmund confirmed this result, but showed that if ethyl acetate be substituted for sugar, the velocity of change is increased by pressure, possibly owing to the sugar being changed into a less, and the ethyl acetate into a more easily hydrolysed modification. A further addition to our knowledge of the matter is made by O. Stern, in the current number of *Wiedemann's Annalen*. He finds that the rate of inversion of sugar by weak acids (acetic and phosphoric) is increased by pressure, while with strong acids (hydrochloric, sulphuric, and oxalic) it is decreased. The author gives his results without comment; it is, however, striking that an increase of velocity is found only with the weak acids, *i.e.* those which are dissociated into their ions, under ordinary pressure, to a small extent only; with these acids a considerable increase in the number of dissociated molecules is possible; with the strong acids, however, this is not the case, because they are almost completely dissociated at ordinary pressure. Taking into account the influence which the pressure has on the body undergoing hydrolysis, some sort of interpretation of the results may be given.

WITHIN the past few days, a number of new editions of scientific books have been received. Messrs. C. C. Hawkins and F. Wallis's simple and accurate volume on the theory, design and manufacture of "The Dynamo" (Whittaker and Co.) has passed into a second edition. The book well combines the theoretical and practical sides of electricity.—"Select Methods in Inorganic Quantitative Analysis," by Prof. Byron W. Cheever, has been revised and enlarged by Prof. Frank C. Smith, and the third edition is now published by Mr. William F. Clay, Edinburgh. In this volume the methods to be followed in the chemical analysis of a set of substances are described, and also the methods of calculating and preparing volumetric standard solutions. The contents thus provide a beginner's course of gravimetric and volumetric analysis.—Another, but much larger, manual to assist beginners in the practice of quantitative analytical chemistry, is "A Manual of Quantitative Chemical Analysis" (Henry Holt and Co., New York), by the late F. A. Cairns, the third edition (revised and enlarged) being by Prof. Elwyn Walker. The book was first published in 1880, and the important changes and advances which have been made since then have necessitated a very thorough revision. The chief feature of the work is mineral analysis, and in the treatment of this branch of analytical practice, as well as of others, students will find very helpful instructions, whilst from it professional chemists will derive useful suggestions.—Messrs. Longmans, Green, and Co. have just published a new and enlarged edition of Mr. G. S. Newth's excellent volume on "Chemical Lecture Experiments." The work contains full directions for the preparation and performance of experiments for illustrating, in lectures, the properties of the non-metallic elements and their more important compounds. Most teachers of chemistry know Mr. Newth's very serviceable volume; those who do not, should hasten to make themselves acquainted with it.

ALL the physical geography required by pupil-teachers and masters in elementary schools is set forth in an orderly manner in "Graphic Lessons in Physical and Astronomical Geography," by Mr. Joseph H. Cowham. The book, which is published by the Westminster School Book Depôt, and by Messrs. Simpkin, Marshall, and Co., is now in its sixth edition. The lessons in it are admirably arranged, the important points in each of them being given prominence. The illustrations are very instructive, and most of them are suitable for sketching upon the blackboard. In fact, the book furnishes strong evidence of the attention paid by the author to the methods of teaching his subject, as well as to the subject itself.—The tenth edition of "The Pocket Atlas of the World," by Mr. J. G. Bartholomew, comes to us from Messrs. John Walker and Co. The "Atlas" has been greatly ampli-

fied and extended. Without increasing its bulk, seventy-two new plates have been added; the text has been rewritten, and the maps revised to the date of issue.—"A Text-book of Shades and Shadows and Perspective," prepared for the use of students in technical schools, by Prof. John E. Hill, has reached a second edition. The book, which is published by Messrs. John Wiley and Sons, has been thoroughly revised and, in the main, re-written.—Messrs. Cassell and Co. have commenced the issue of a cheap edition of their "Technical Educator." The parts will appear weekly, and each will contain ninety-six pages of text and illustrations.

THE additions to the Zoological Society's Gardens during the past week include two White-thighed Colobus (*Colobus vellerosus*, ♂ ♀), a Campbell's Monkey (*Cercopithecus campbelli*, ♂), a Green Monkey (*Cercopithecus callitrichus*, ♂) from West Africa, presented by Dr. S. H. Armitage; a Lesser White-nosed Monkey (*Cercopithecus petaurista*) from West Africa, a Black-headed Lemur (*Lemur brunneus*) from Madagascar, presented by Miss Baird; an Arabian Gazelle (*Gazella arabica*, ♂) from Arabia, presented by Mr. R. G. Buchanan; two Raccoons (*Procyon lotor*) from North America, a Golden Eagle (*Aquila chrysaetus*), a Buzzard (*Buteo vulgaris*), European, presented by Lord Arthur Cecil; two Laughing Kingfishers (*Dacelo gigantea*) from Australia, presented by Mr. F. Beaumont; five Eyed Lizards (*Lacerta ocellata*), European, presented by Mr. P. Goupille; a Thick-necked Tree Boa (*Epicrates cenchris*) from Tropical America, deposited.

OUR ASTRONOMICAL COLUMN.

LEONID METEORS IN AMERICA.—The display of meteors on November 13 and 14 is said to have been great at some places in America. Published accounts include the statement that as many as twelve at a time were seen; and a press dispatch from Indianopolis states that meteors were visible there in broad daylight, in fact about the middle of the day.

A NEW SPECTROSCOPIC BINARY IN PUPPIS.—A new addition has recently been made to that class of stars of which ζ Ursæ Majoris, β Aurigæ, and μ Scorpii are the present members. The star in question is Lacaille 3105, A.G.C. 10534, and the Draper Memorial photographs show that it is a binary, its photometric magnitude being 4·50 (*Harvard College Obs. Circular*, No. 14). Prof. E. C. Pickering first noticed its binary character in February of last year, and this has been corroborated by several photographs secured by Prof. Bailey. A discussion of all the photographs taken, gives the length of the period as 3d. 2h. 46m., the formula representing the times of inferior conjunction being given as J.D. 2412777.16 + 3·115 E.

At these times the lines in the spectrum are said to be single; for the next thirty-seven hours they are double, the fainter component of each having a greater wave-length than the brighter component. The lines then again become single, and finally double for the remainder of the period, the fainter components having shorter wave-lengths, and being therefore towards the violet end of the spectrum.

RELATIVE MOTION IN THE LINE OF SIGHT.—In a *Harvard College Observatory Circular* (No. 13), Prof. E. C. Pickering describes a new method by which the relative motion of stars in the line of sight may be determined by means of the objective prism. As yet only preliminary trials of this method have been made, but it promises, as we are told, to be fairly satisfactory. In a discussion with Mr. E. S. King, of the experiments made by comparing the corresponding lines in the spectra of different stars with their images taken on another plate without the prism, and with the film reversed, the following process was evolved. It may be briefly summed up as follows. Two stars which are close enough to be photographed on a single plate are first selected. Let one of these be supposed at rest, and the other moving, say, towards the observer with a velocity represented by a deviation of amount d in its spectrum. If a photograph be taken such that the end of the shorter wave-length of the moving star be turned towards that of the star at rest, the distance between the images of a given line in the two spectra will be lessened by the amount d. By turning now the prism through 180°, the spectra will also be rotated through the same amount, and the end of greater wave-length of the spectrum of the moving star will now be turned towards that of the star at rest. If a photograph be taken in this position, the distance will in this case be increased by d. By superposing the two photographs thus obtained, making the images of the given line in the spectra of the star at rest coincide, the difference in the readings of the same line in the other spectra gives double the displacement of this line.

In actual practice the photographs can be obtained one on each side of the meridian, the act of reversing the telescope turning the prisms, and with them the spectra, through 180°.

For the examination of the plates, the film sides of the negatives must be placed together to ensure an accurate comparison, thereby necessitating that one of the photographs has to be obtained with the film side *away* from the objective prism. The question of change of focus can here then arise, of which, however, Prof. Pickering makes no mention.

The advantages of this method, as stated by him, may be condensed as follows:—Directness of the determination of the motion. Double the deviation is measured. Accidental errors of measurements are much less than when each in turn is bisected by a spider line, as the ends of two similar lines are made to coincide. Since each line in the spectrum may be used, a large number of independent determinations may be obtained from one pair of plates. Further, a visual telescope may be employed, as it is only *necessary* that one line should be in focus. Corrections for the motion of the sun in space, or of the earth in its orbit, may be disregarded, as they affect both stars equally.

FORMULÆ FOR COMPUTING WAVE-LENGTHS.—By the investigations of several workers the positions of the lines in the spectra of numerous substances are being mathematically determined. It was Lecoq de Boisbaudran who first pointed out the regularity in position in which lines of some substances appeared. Stoney, and others after him, found out that some of the lines of hydrogen were harmonically situated in the spectrum. It was left, however, for Balmer to bring forward a formula by which the wave-lengths of the lines in the hydrogen spectrum could be computed with wonderful accuracy. The formula was as follows:—

$$\lambda = A \frac{n^2}{n^2 - 4},$$

where n represented the numbers 3 to 15, and A the number 3645·42 in Ångström's units. Cornu at the same time, and Deslandres a year later, worked on this question, the latter producing a formula from which the bands of several elements could be computed.

In 1887 Kaiser and Runge set to work, and between them they advanced the new idea very considerably by describing a general formula which represented a great number of series of different elements, and which also included that of hydrogen, Balmer's formula being found to be only a special case. The new formula became then

$$\tau_n = A - Bn^{-2} - Cn^{-4},$$

the reciprocal of the wave-lengths (τ_n), instead of the wave-length themselves being here employed. The first three members of such a series sufficed to represent the series of lines with considerable approximation from values obtained from observation, with the exception, perhaps, of the longest and shortest waves. For the determination of these constants, which appear in this formula, three distinct measurements of the number of oscillations are necessary.

The drawback of this formula is that for the longest, or, at any rate, the two longest waves, it is not sufficiently accurate; and, even if more terms were added, the determination of the values of the additional constants would be uncertain owing to the limited accuracy of the wave-length measurements.

In determining the accuracy of this expression, Messrs. Kaiser and Runge were thus led to undertake the investigation of more accurate determinations of the spectra of the elements.

More recently, however, Herr Balmer has succeeded in finding an expression which represents the series with greater accuracy than formerly. This differs slightly from those given above, in that the third term is dispensed with, and an additional constant

is placed in the denominator of the second term. The expression is

$$\tau_n = A - B/(n + c)^2.$$

That this is capable of giving results of very considerable accuracy is shown by its application in the case of the spectrum of helium, these results being given in the *Verhandlungen der Naturforschenden Gesellschaft in Basel*, Band xi. Heft 3, a "Separatabdruck" of which paper we have before us. All six series of lines in the spectrum have been computed, and in every case the differences, observed minus calculated, are small. Herr Balmer describes also a method by which the line series can be graphically constructed.

THE "LINCEI" AND EXPERIMENTAL SCIENCE.[1]

IN accepting the invitation to deliver an address on the twenty-first anniversary of the revival of this Academy, when it added social and philological science to mathematics and physical and natural science, I have from the outset not ignored the difficulty of my task, which I have since found even greater than I expected. Nevertheless, a consideration of the work done by the first Lincei, who founded this most ancient of all existing scientific Academies, and a notice of their contribution to the progress of all experimental sciences, particularly biology, appeared to me a subject worthy of your attention.

Federico Cesi, founder of the Lincei, leaving Rome in 1618, handed over to D. Virginio Cesarini, and Giovanni Fabri, Fellows, the mission of giving the ring of the Lincei to Carlo Muti. Cesarini subsequently wrote to Cesi that he had instructed the newly-elected Fellow in the usages and rules of the Academy, and "particularly in the liberty of conscience, love of truth, confession of ignorance, and also, so far as my poor intelligence can, I have not failed to open to him the true founts of human science, not dialectic but real, praising mathematics and natural science as the sole and only principles by which to gain knowledge in this world." The extract, which I have taken word for word, shows clearly the method by which alone the Lincei believed scientific truths could be sought out; and we should have known it more exactly but for the loss of a manuscript, by Cesi, on the "Universalis rationis speculum in quo universalis ars continetur." Still, we do know that at the first meeting, held October 15, 1603, Giovanni Eckio described the operation of the mind, by which it proceeds from facts to conceptions; that is to say, he spoke of induction.

The Lincei were not content with philosophising, but made experiments on subjects pertaining to natural and medical science: and set themselves to observe and calculate the motions of the stars. To this end they provided apparatus and instruments, including the telescope and the microscope, which latter they were the first to use, making known its advantages in the study of botany and zoology. The first print of a microscopic object is that by Francesco Stelluti, representing the honey bee, and placed as frontispiece to the *Apiarium* by Cesi, published in 1625.

The Lincei were also the first who instituted experiments to solve the question of the generation of living objects from putrefaction, an opinion then universally held. We find that Cesi was the first to recognise the animal nature of sponges, corals, and fresh-water polypi; that he maintained there was a gradual transition between the three natural kingdoms, and that he discovered fossil wood. For their method of pursuing science, the Lincei were persecuted from their very first meeting in 1603, and so bitterly, that they were obliged to separate and keep apart for several years. The Lincei had been preceded by Leonardo da Vinci, who held induction to be the only legitimate method in natural science; by Andrea Vesalio, who had overthrown Galen, insisting on the direct study of human anatomy; and by Niccolo Copernico, who subverted the Ptolemaic system, and established the sun as the centre of our planetary system around which the earth and other planets revolve.

On another side, the ground for scientific research had been prepared by the Florentine Platonic Academy, who had substituted Plato for Aristotle, and had grafted platonic idealism on the growing sentiment of Christian art. It was necessary, however, to free science from the spirits of the alchemists, from the idealism of the neoplatonists, from the teleological argument of the scholiasts; in a word, from every trace of transcendency, and of finality, so that the human mind, being freed from prejudices and preconceptions, might be enabled, through the study of nature, and by the aid of mathematics, observation, and experience, to seek the real causes of phenomena. This was the work initiated by the Lincei, this was the innovation, deemed bold and dangerous, which gave rise to the new philosophy—Natural Philosophy—which in its turn originated the great scientific movement culminating in a Galileo, a Bacon, and a Descartes.

Galileo lived in the scientific atmosphere of the Lincei (to which Society he was elected in 1615), and he is held to be the founder of the experimental school, proceeding with steady steps in their ways, inventing valuable instruments, and making discoveries of the greatest scientific value. Bacon made no experiments, but gave instead the laws of induction; yet living among such surroundings as those of Elizabeth's court, then swarming with alchemists, notwithstanding his having combated their philosophy and that of the scholiasts with much minuteness, he still believed in spirits, and could not unfetter himself from final causes. Bacon has been accused of not appreciating with exactness the relation between cause and effect, not caring for mathematics, and supposing effects the results of one sole cause, which rarely occurs in nature. Purely inductive methods do not suffice for natural science, for when by them we arrive at one acquired truth, we can from this one deduce others by reasoning, and even rise by mental theories to more general principles. In this sense great credit is due to Descartes, who employed deductive methods, and exhibited the advantages in the study of nature arising from mathematics, as had been already recognised by the Lincei, and used by Copernicus, by Kepler, and, in conjunction with experimental methods, by Galileo.

To demonstrate the importance of the true causes which act on living organisms not solely from their exact value, we might adduce numerous examples taken from the progress made in our own time by medicine, the most practical and beneficent to humanity of all sciences; for if physics and chemistry have by their appliances increased the enjoyments of social life, medicine has succeeded in lightening many of the burdens of suffering humanity. The terror produced by the announcement of a great epidemic, when it was believed to be a chastisement sent from heaven to punish men on earth, ceased from the day when it was found to be the deleterious action of minute living objects, the so-called pathogenic microbes, and when aseptic and antiseptic cure, and the inoculation of attenuated virus and of curative serums were discovered to subdue and destroy the infinite armies of these imperceptible but deadly enemies to mankind, animals, and useful plants. I will not dwell longer on these and other victories of contemporary medicine, my only intention being to treat of science, which does not take account of utility, but is intent on discovering the causes of phenomena. If in practical life we must look to the good of humanity in science, there can be no special ulterior object of any kind. In medicine, however, as in every other science, we distinguish practice, or the application of scientific truths to the benefit of humanity, from science itself. Medicine reaps the benefit of the whole science of life, biology, of which morphology is an essential part, as well as that which seeks the true causes of organic forms in their origin, growth, and involution. Morphology, then, is called upon to solve the problems of organisation; for example, we desire to know why animals and plants leave their present form, in what way species differ or resemble one another, and in what relation they stand to their ancestors. The answer to such queries was at one time easy, but not scientific; when, that is to say, it was believed there was one pre-established type in which individuals were formed and species fixed, the answer was: that the form was what had been created, that consequently species were independent, that their ancestors had for their mission only to bear in their loins germs of such as they had been themselves, created contemporaneously with other matter in determined numbers, and with their form predetermined even to its minutest parts. With this doctrine research flagged, nothing was explained, and from the time of Gassendi (1592-1655), who was the first to formulate it, up to our present century, that is to say, till it was overthrown by the doctrine of evolution, our knowledge of living beings remained stationary. The science of the organisation of living beings, therefore, commenced when the theory of evolution became prevalent.

[1] Abridged translation of an address delivered before the Reale Accademia dei Lincei, by Signor Todaro.

Evolution admits that, as a result of real causes, characteristics may vary and be transmitted to descendants; hence, species are established by transformation from a common origin. Hereditary variation and transmission are the two essentials in the conception of species as now understood by zoologists and botanists, who regard them rather as to what they may become than what they are. This new conception of species has brought about an entire revolution in the study of biology, it being now recognised that individual, or, as it is called, ontogenetic development depends on genealogical or philogenetic development, in which the causes of existence must be sought, and the explanation found of the form presented by animals and plants in the actual state. Various theories, which I will briefly note, have been formulated to explain the action of the causes which produce the astonishing phenomena of variability of character and their hereditary transmission. The first of these theories, natural selection, which tried to explain everything, has had its day, and now is only invoked to account for certain secondary characteristics, or those attributed to the adaptations of individual forms. In fact to admit, with Darwin, the selection of properties subservient to their purpose, such as would arise in the struggle for existence, in which the strongest would survive, is the same as introducing a teleological cause into the explanations of nature, where no struggles nor purpose exist, but only phenomena which are in the relation of cause to effect, as had been established by natural philosophy. The principle of improvement from internal causes, propounded by Nägeli, is but the affirmation of a result of which the causes, not only internal but also external, acting and reacting on each other, still remain to be found. Julius Sachs accepts improvement from internal causes, but adds mechanomorphosis produced in plants by mechanical means, such as the action of light and of gravity.

To study the effects of physico-chemical, or mechanical causes in living bodies, Roux has lately formulated his biomechanical theory, which is far more scientific than the old mechanical theory of Descartes. Nevertheless the author does not take into account development, which is the fundamental principle of evolution, and in consequence of which forms and structures cannot all be explained solely by actual causes; since we must not lose sight of the idea that actually existing forms are essentially the product of causes which have operated slowly and successively in time. Roux, wishing to give the explanation of the trabecular structure of the liver, and the multipolar form of the hepatic cells of adult mammals, refers the cause of the orientation of the above-named cells to the action of material exchange, and which, from the bipolar form they take in all glands, have become transformed into multipolar cells in the liver of adult mammals. Hence, he refers also to this cause the transformation into fine network of the nutritive circulation which from tubular has become trabecular. But the case given by Roux leads us to one conclusion only, namely, that the elements, tissues, and organs are so closely correlated, that no alteration can take place in one without necessarily occasioning alteration in the others. But to know how the liver of adult mammals has become trabecular, and its hepatic cells multipolar, it is necessary to investigate the history of its genealogical development, such a transformation being effected by causes which have worked in time.

Can this investigation be made? Surely, by not limiting ourselves to the bare testimony of our senses, but by taking advantage also of induction. Comparing the liver of the adult with the liver of the embryo of the same mammals and with the liver of the other vertebrates, observation shows that in the embryo of mammals the liver is tubular, exactly as it is found in inferior vertebrates, even in the adult stage; hence we have been able to conclude that there was a period when, in the ancestor of the mammals, the liver was tubular through its whole life, and that the trabecular form is a later development. Thus far it is true we have not pointed out precisely what is the cause, or rather what are the causes which have transformed the gland from tubular to trabecular; but can we fill up this hiatus by the study of present causes? In the example under consideration, when we know that the nutritive current runs in one case only in one direction, and in the other in various directions, we cannot yet say that we therefore know the cause or causes of such variations, since we do not know precisely what were the causes, external and internal, which produced the alteration in the material exchange. Only by comparative research of organic forms we find that the trabecular form of the mammals is derived from the tubular form, and we thus come to an important result, thanks to which we can establish the parentage of animals—namely, that in the embryo are registered the genealogical documents of the race of his ancestors; and if we can but read them we shall find them, although more or less modified. Usually the more recent are the more clearly imprinted, while it is difficult to decipher the very old ones; indeed, sometimes these are entirely lost. We have an example in the development of the Molgulidæ and of the Salpæ, which, together with the Ascidians and other forms, constitute the class Tunicata.

The larvæ of the Ascidians pass through two phases of development; in the first, they present the cordate type, which subsequently disappears, being transformed in the second phase into the definite and exact type of the Tunicata. Now, in the Molgulidæ and in the Salpæ the first phase is suppressed; the cordate type is not repeated, and development commences directly from the Tunicata type. Without the Ascidians we should be unable to establish the relationship of the Tunicata with *Amphioxus* and the Vertebrates; and the class Tunicata would have remained where at one time it was placed, between worms and molluscs. Now, thanks to historical and philogenetic research, we know that a high place awaits the Tunicata beside the Cordata and the Vertebrates; and we are led to admit that these three great classes have a common origin, the Protocordatus, which has disappeared, but which we can reconstruct from the characteristics we meet with in these three classes.

The reconstruction of extinct organisms, which we are able to effect by the study of morphology, demonstrates the highest function of this science; the veracity of such reconstructions has been sometimes confirmed by successive zoological and palæontological discoveries. From the fundamental characteristics we meet with in the embryos of Ascidians, *Amphioxus* and the Vertebrata, we can affirm with certainty that the common progenitor of the Tunicata, the Cordata and the Vertebrata, had the form of a fish; possessed an intestine divided into an anterior part chiefly respiratory, and a posterior part digestive; had a body divided into segments, a spinal cord, and a nervous dorsal tube decurrent from its anterior to its posterior extremity, an arterial longitudinal dorsal vessel and a venous ventral one. Here, then, is one of the important results achieved by science through the study of organic forms.

Nor have results of lesser importance been obtained by researches on heredity. Progressing by experiment; aided by optical appliances, which in our day have made astounding progress, and by which the microscope has been raised to a high pitch of perfection; furnished with the most precise and delicate methods of modern histological technique, by which every living element can be detected in the various phases of its activity; we have succeeded in discovering an important part of the secrets with which nature has surrounded the generation of living beings, secrets which naturalists of time not long past had declared impenetrable.

Guided by experimental methods, we may hope that science will be able ere long to solve complex and important questions relating to the organisation of living bodies; we seek not the nature of things, which is impossible for us to learn, but the true reason of phenomena, remembering what the Lincei had affirmed from their very first institution—liberty of conscience, love of truth, confession of ignorance.

THE NATURAL IMMUNITY OF VENOMOUS SNAKES

IN a previous article (NATURE, October 24, 1895, p. 621) the "Serum Treatment of Snake-bite" was briefly discussed by the writer of this note; and Calmette's and Fraser's researches are now so well known, that it is not necessary to give a summary of them. One or two points, however, must again be alluded to, because recently Dr. D. Cunningham, of Calcutta,[1] has carried on some important experiments which throw fresh light on the matter, and which also supply answers to some of the questions raised by the writer in the above-mentioned article.

The most surprising conclusion of Calmette and Fraser was that the serum of an animal immunised against cobra poison will protect not only against this poison, but also against the poisons of other snakes. It might be thought that this is an argument against Behring's law that the action of immunising serum is

[1] "Scientific Memoirs by Medical Officers of the Army of India," 1895, ix. p. 1–30.

specific, *i.e.* that such serum can only counteract that virus against which the animal supplying the serum has been immunised. Most snake poisons, however, are so similar in their chemical nature and physiological action, that it is hardly surprising that chemically similar poisons which, according to their action on the animal body, belong to one physiological group, should have the same antidote. In the former article the writer pointed out that there is one poison, daboia poison, which, as shown by Cunningham and Wall,[1] differs from cobra venom in its physiological action; and that therefore one could hardly expect that (*a*) animals immunised against cobra poison would become resistant against daboia venom, and *vice versâ*, and that (*b*) a serum capable of acting as an antidote to cobra poison would also be capable of neutralising daboia venom.

By a series of experiments performed at the Calcutta Zoological Gardens, in 1895 and 1896, Cunningham[2] has supplied these *à priori* considerations with a sound basis of fact. He shows that a fowl immunised against daboia venom by means of an habitual cumulative treatment with that poison does not acquire a corresponding immunity from cobra venom; and conversely, that the serum derived from the blood of animals which have been artificially immunised against cobra venom has no effect whatever as an antidote to daboia venom. The results are precisely what had been anticipated by the writer from the perfectly distinct properties of the two poisons. It is therefore not possible, so far as our present knowledge goes, to establish a vicarious immunity against absolutely dissimilar poisons, and Calmette's statement that a serum prepared from animals protected against cobra venom is an antidote against the action of the venom of *all* poisonous snakes requires some correction. These experiments then strongly support Behring's law, and we must perforce adhere to the principle of the specificity of immunising serum: distinct toxins require distinct antitoxins.

Fraser[3] has asserted that the serum or blood of poisonous snakes possesses antitoxic powers, and has explained the snake's natural immunity from its own poison by assuming that it immunises itself by swallowing its own venom, and thus renders its blood antitoxic. In 1892, already the writer,[4] working in India with freshly-caught cobras, was unable to obtain any real antitoxic effects with the serum of a normal cobra. Cunningham has since devoted full attention to this matter, and shows conclusively that the serum of a normal cobra, whether it be administered together with, before, or after the poison, has no antitoxic action whatever, and one must agree with him "that the natural immunity of cobras is perfectly distinct in its nature from the artificial immunity which is established in other animals as the result of continued treatment with cobra venom, and that it is unconnected with any material of the nature of an antitoxin in the blood." Normal cobra serum has also no antidotal effect on daboia venom, although the cobra enjoys an extraordinary immunity against this venom. In the previous note it had already been maintained by the writer, that since a large number of innocent snakes are highly resistant against cobra poison, although they never ingest poison, it is almost impossible to regard the natural immunity of venomous snakes as being due to habitual ingestion of their own poisons. All we can say is that a number of reptiles and amphibia possess a high degree of resistance as a natural property or character, independent of any process of self-protection, whether by swallowing or inoculation. In a few interesting experiments Cunningham, moreover, clearly shows that the inoculation of a poisonous snake with its own venom does not lead to the production of antitoxic substances in its blood. This is important, because it might have been assumed that, whilst normal cobra serum possesses no antidotal properties, serum derived from cobras in which self-inoculation had taken place, might have become antidotal. One of Cunningham's cobras readily resisted inoculation with an amount of cobra venom sufficient to kill 1000 fowls, and yet its serum had no preventive action whatever on even the minutest dose of the poison. But what is stranger still: a fowl was inoculated with 3 cc. of serum from a cobra which had received '75 gramme of cobra venom. Considerable drowsiness followed, and sixty hours later the bird died of typical cobra poisoning. The blood of the snake, therefore, which had been killed a week after it had been inoculated with a large dose of cobra poison, contained enough unaltered venom to give rise, on injection into a fowl, to fatal intoxication, although the snake itself had shown no symptoms. In other experiments Cunningham obtained the same result, viz. "that the serum of cobras treated with excessive doses of cobra venom has no protective action whatever, but may for some time contain enough unaltered venom to give rise to fatal intoxication in susceptible animals." Is it possible, then, that the natural immunity of poisonous snakes is due to the presence of the same antitoxic bodies which are called into existence in susceptible animals by a process of slow and gradual immunisation? Are not the conditions exactly parallel to those which we find in natural immunity from bacterial diseases? It is there quite exceptional to find that the serum of naturally immune animals possesses any bactericidal, immunising or antitoxic properties towards the bacteria or their toxins, from which the animals enjoy a natural immunity. We must come to the conclusion, at which both Cunningham and the writer have previously arrived, viz. "that snakes as a group appear to be relatively insusceptible to the action of cobra venom, whether they be poisonous or harmless."

Cunningham further believes that there is good ground for assuming that the degree of susceptibility, to some extent, runs parallel with that of respiratory requirement. Thus a *Zamenis* (*Ptyas*) *mucosus*, or "common rat-snake," may be submerged in water, without being the worse for such treatment, for about half an hour, and it may be exposed to an atmosphere containing a large amount of CO for at least two hours, without being in the slightest affected thereby. This parallelism between susceptibility to cobra poison and respiratory requirement, to some degree at least, holds good also for other cold-blooded animals. Thus the *Varanus salvator* is extremely resistant against the effects of cobra poison, and it is still more indifferent to submersion. That immunity from intoxication with cobra poison does not, however, depend entirely upon a low degree of respiratory requirement becomes clear, as Cunningham distinctly states, when we compare the Zamenis with the Varanus; for the former, which is much more rapidly drowned than the Varanus, possesses a far higher immunity than the latter. Certain *Lacertilia*, again, are as susceptible to cobra poison as fowls; but Calmette is wrong in stating that a high susceptibility is a general Lacertilian peculiarity. The *Calotes versicolor* is quickly killed by cobra poison, but it is also rapidly affected by submersion. Batrachia, however, which have a low respiratory requirement, are relatively insusceptible to cobra venom. Hence, although the natural immunity of these animals does not entirely depend on their low respiratory requirement, this property is a factor of great importance; but however this may be, the natural immunity of poisonous snakes certainly does not depend on a process of self-immunisation. It would be interesting in this connection to study the natural immunity of freshly-hatched cobras, which, it is said, are venomous from their birth.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—On December 1, Convocation decided to affix the University seal to a memorial to the Duke of Devonshire, Lord President of the Council, desiring that a central educational authority for secondary schools be created.

Dr. J. S. Haldane has been reappointed Lecturer in Physiology for three years from January 1, 1897.

Messrs. E. E. Blackburn, E. E. Marsh, and F. A. Storr have satisfied the examiners in the second part of the examination for the Diploma in Public Health.

The Hebdomadal Council has accepted an offer from Prof. Poulton to present a statue of Charles Darwin for the court of the University Museum.

A bust of Sir Henry Acland is about to be placed in the court of the Museum as a memorial of his services to the Oxford Medical School.

Mr. H. B. Hartley, of Dulwich College, has been elected to a Brackenbury Natural Science Scholarship, and Mr. L. K. Hindmarsh, of King Edward's School, Birmingham, to a Natural Science Exhibition at Balliol College

Mr. R. E. Thwaites, of Batley Grammar School, has been

elected to a Millard Scholarship in Natural Science at Trinity College.

Messrs. G. W. Williams, of Pocklington School, and H. H. Crosthwaite Thomas, of Kendal School, were honourably mentioned as a result of the examinations for Hasting's Exhibitions at Queen's College.

The following elections to Mathematical Scholarships and Exhibitions have taken place:—Balliol College: H. C. Beaven, of Rugby School; W. H. Beveridge, of Dulwich College. Queen's College: R. B. Threlfall, of Heversham School. Brasenose College: F. F. Beach, of Monmouth Grammar School. Worcester College: O. Meade-King, of Exeter Grammar School; W. C. Burnet, of Boston Grammar School.

CAMBRIDGE.—The Arnold Gerstenberg Studentship for promoting the study of moral philosophy and metaphysics among students of natural science, both men and women, has been divided between Mr. C. S. Myers, of Caius College, and Mr. A. G. Tansley, of Trinity College, who have already taken honours in the Natural Sciences Tripos.

A vote of the Senate will be taken to-day (December 10) on the question whether or not the Sedgwick Memorial Museum of Geology shall be erected in the ground recently acquired from Downing College.

The General Board of Studies, while adhering to their opinion as to the importance of maintaining and endowing the Professorship of Surgery, now propose that it shall be suspended for one year. The proposal is made on the ground that it is desirable to give time for bringing about an official connection between the office and "a Hospital." Of course Addenbrooke's Hospital is intended, and it remains to be seen whether the Governors will be willing to reopen a question which was thought to have been satisfactorily arranged a few months ago.

The State Medicine Syndicate states that in the past year sixty-seven candidates have presented themselves for the examination in Public Health. Thirty-five were successful in obtaining the University Diploma.

Mr. E. W. Brown, of Christ's College, Professor of Applied Mathematics at Haverford College, Pennsylvania, has been approved for the degree of Doctor of Science. Prof. Brown's researches in the lunar theory are numerous and important.

Dr. L. E. Shore, Fellow of St. John's College, has been appointed University Lecturer in Physiology, in the place of Dr. A. S. Lea; and Mr. A. Eichholz, Fellow of Emmanuel College, has been appointed an additional Demonstrator in Physiology.

Mr. F. B. Stead, of King's College, has been nominated to occupy the University's table at the Naples Zoological Station, in the place of the late Mr. Gray.

The Walsingham Gold Medal has been awarded to Mr. W. McDougall, of St. John's College, for a monograph embodying original research in physiology.

THE Gossage Chemical Laboratory of the University College, Liverpool, will be opened on December 12, by the Earl of Derby. Prof. Ramsay will deliver an address upon that occasion. This addition to the chemical department will, says the *British Medical Journal*, afford increased accommodation to medical students and candidates for the D.P.H., and will provide the means of carrying on special advanced chemistry. In connection with this department it is proposed to undertake the preparation of some of the rarer chemical compounds for the use of investigators who now have frequently to send abroad for them.

THE regulations applicable to secondary schools receiving grants from the Technical Education Board of the London County Council for the year 1896-97, which are published in the last number of the *Gazette*, are of a very satisfactory and thorough kind. Amongst several important additions and alterations, we are glad to notice that scholars entitled to free education are not to be required to pay for entrance fees, books, examination fees, or other extras. The arrangements which continue to be made towards perfecting the practical teaching of science in the metropolitan secondary schools leave little to be desired. In the issue of the *Gazette* before us we find an account of additions to six more of these schools, viz:—Cooper's School, Bow; Philological School for Boys, Marylebone Road; Roan School for Boys, Greenwich; James Allen's School for Girls; Brompton School for Girls; and Rame's School for Boys, St. George's-in-the-East. In nearly every case laboratories for the teaching of practical physics and chemistry have been provided, and in some of them manual instruction has also been added to the curriculum.

THE Catalogue (*Anglice*, Calendar) of the Michigan Mining School for 1896-1898 has lately been issued. Beside the usual school statistics, cuts of buildings, outlines of courses, &c., the volume contains a number of tables giving the classification of rocks and minerals, which students taking the course in geology, mineralogy, and petrography will find very valuable in their class and laboratory work, as well as helpful in their future researches. The scope of the work done and the methods employed in this department of the school are well outlined by these classifications. The catalogue contains also various statistics concerning the mineral production of the United States, and of Michigan in particular. Mention is made of the equipment and work of many of the most important copper and iron mines in the Upper Peninsula. The data thus collected brings out the fact that the school has all that could be desired in its situation, in the very midst of the most productive mines, in which are found the finest mining machinery in the world. The weekly excursions to the neighbouring mines and mills, laid out as a regular part of the student's work, together with the annual trip to the more remote iron mines, enable him to study and compare the plans of work employed.

MR. BALFOUR'S remarks, reported in NATURE (p. 85), upon the difference between technical instruction as understood by most of the committees which dispense it, and the higher technical instruction in which Germany takes the lead, ought to be known to every local educational authority in the country. The matter was referred to in a recent address, (p. 69), in which Prof. Meldola deplored the action of Technical Education Committees in frittering away the fund at their disposal upon numerous small classes, instead of concentrating their attention upon a few, and making these thorough. The folly of this has been pointed out on many occasions in these columns, and every thoughtful educationist regrets that so much money is being wasted upon trade subjects while the scientific principles underlying them are generally neglected, and often ignored altogether. With the idea of finding the nature of the instruction given in technical classes, we have looked through the invaluable *Record* published by the National Association for the Promotion of Technical and Secondary Education, and have derived therefrom the following instances:—

In addition to classes in other subjects, Bedfordshire provides instruction in nursing, carpentry, and farriery; Buckinghamshire supplies dressmaking, lace-making, straw-plaiting, horticulture; Cambridgeshire: basket-making, brick-work, vocal music; Isle of Ely, poultry-rearing, bee-keeping, ploughing, draining and dyking, vocal music; Cheshire, pattern-cutting and clicking, type-writing, music; Cornwall has classes in cabinet-making and plumbing; Devonshire, sheep-shearing and thatching; Dorsetshire, brick-making; Essex, smiths' work, sail-making, photography; Herefordshire, ploughing and hedging, précis-writing, horse-shoeing, and political economy; Hertfordshire really distinguishes itself by providing for instruction in nineteen "technical" subjects, including embroidery, wicker-work, china-painting, allotment gardening, hedging and ditching, sheep-shearing, ploughing, and farriery. Lancashire encourages the teaching of subjects which differ as widely as "hat-manufacture" and "financial science." The difficulty experienced in reading the report of the work in Lancashire was to find some subject which was *not* taught. Leicestershire adds "hosiery" to its repertoire, and Lincolnshire (Holland) stacking. Norfolk provides on its "bill of fare" every subject from needlework to seamanship. Shropshire adds leather-work, a subject favoured by many other counties. Staffordshire offers metal-work, repoussé-work, and gesso, while Surrey is distinguished by "economics." East Sussex fosters music, and teaches life-saving. Wiltshire sanctions classes in brewing, and Worcestershire in cider-making. The borough educationists are disposed in many cases to be inventive. At Bath "technical arithmetic" has been invented, at Bolton "machine" calculations are taught as a separate subject, while the youth of Burnley are taught "commercial" English. The authorities at Blackburn assist the teaching of Greek and Latin, in addition to French, German, Spanish, Italian, and Portuguese, and add thereto the usual subjects, with vocal music, shorthand, and book-keeping. These instances are but a few of many which can be found in the *Records* for the last two years. No further argument is necessary to show the necessity for some sort of unanimity as to what ought to be attempted and what left alone. The worst of it is that all this dabbling dissipates energy which, with a little guidance, could be made capable of accomplishing really useful work.

SCIENTIFIC SERIALS.

Symons's Monthly Meteorological Magazine, November.—The climate of the British Empire in 1895. The values for that year present one unusual feature: the highest shade temperature (107·2°) was recorded at Calcutta, being apparently the highest reading there in the past fifteen years; the maximum is generally recorded at Adelaide. For extreme cold, Winnipeg (−45·5°) is unapproachable; this station has also the greatest annual range (133·8°), and the greatest mean daily range (23·0°). The driest station is Adelaide, mean humidity 59 per cent.; and the dampest, Esquimalt, 89 per cent. The highest temperature in the sun was 178·0°, at Trinidad, and the lowest temperature on the grass, −27·0°, at Toronto (the minimum temperature on the grass is not recorded at Winnipeg). Colombo, Ceylon, had the greatest rainfall, 92·23 inches, and Malta, the least, 11·38 inches. The greatest amount of sunshine occurred at Bombay and Jamaica.—The scientific use of kites. An account is given of the recent experiments at the Blue Hill Observatory; these have already been referred to in our columns. The Washington Weather Bureau is also giving great attention to the subject, and has requested Prof. Marvin and others to make a special study of this branch of meteorological research.—This number also contains notes on the first use of the word "isobars," and on meteorological observations in schools; the latter subject has already been noticed in our columns.

In the *Nuovo Giornale Botanico Italiano* for October, Sig. A. Preda concludes a very elaborate paper on the Italian species of *Narcissus*. In addition to an enumeration of the species, a detailed account is given of the structure of the flower and other organs of the plant, especially of the nature of the corona, and of the mode of pollination.—Sig. E. Migliorato discusses the nature of the spines in the *Aurantiaceæ*, which he decides to be of cauline, and not foliar origin.

In the *Journal of Botany* for November, a very interesting addition to the British flora is recorded by Mr. F. Townsend, in *Euphrasia salisburgensis*, gathered by the Rev. E. S. Marshall in Co. Mayo. The species is an eminently Alpine one, being found at elevations between 3400 and 7800 feet in Switzerland. It appears to find its lowland limit in Ireland, where it occurs almost on the sea-level.

SOCIETIES AND ACADEMIES.

LONDON.

Chemical Society, November 19.—Mr. A. G. Vernon Harcourt, President, in the chair.—The following papers were read:—Sulphocamphoric acid and derivatives of camphorsulphonic acid, by A. Lapworth and F. S. Kipping. Sulphocamphoric acid $SO_3H.C_8H_{13}(COOH)_2$ is obtained by oxidising α-bromocamphorsulphonic acid; its sulphonic chloride is converted into π-chlorocamphoric acid by heat.—A compound of camphoric acid and acetone, by W. J. Pope. Camphoric acid crystallises from acetone in crystals having the composition $C_{10}H_{16}O_4$, $\frac{1}{2}Me_2CO$; they are crystallographically closely related to camphoric anhydride.—Mercury hyponitrites, by P. C. Rây. A solution containing both mercurous and mercuric nitrites is obtained by the dissociation of mercurous nitrite; on adding sodium hyponitrite, mercurous and mercuric hyponitrite are formed.—The nitrites of mercury and the conditions under which they are formed, by P. C. Rây.—The interaction of mercurous nitrite and the alkyl iodides, by P. C. Rây. Apparently ethyl nitrite and nitroethane are formed in the interaction of ethyl iodide and mercurous nitrite.—Crystallography of the monohydrated mercurous nitrite, by T. H. Holland.—On the identity of dextrose from different sources; with special reference to the cupric oxide reducing power, by C. O'Sullivan and A. L. Stern. The optical activity, cupric oxide reducing power, and the specific gravities of aqueous solutions of dextrose prepared from cane and beet sugar, starch and lactose have been determined; the factors thus obtained are the same for the various samples of dextrose, so that it is concluded that the latter are identical.—Note on Mr. W. J. Humphreys' paper on the solution and diffusion of certain metals in mercury, by Prof. Roberts Austen.—Solution and diffusion of certain metals and alloys in mercury: Part II., by W. J. Humphreys. The author has investigated the rate of diffusion of aluminium, antimony, cadmium, magnesium, thallium, and a few alloys in mercury; he considers that solution and diffusion in mercury may serve to distinguish between mixtures and compounds in the case of alloys.—Note on the heat of formation of the silver amalgam Ag_2Hg_8, by Miss F. T. Littleton. The heat of formation of the amalgam Ag_2Hg_8 is about +3432, and its specific heat is 0·029; the specific heat calculated from those of the constituent metals is 0·0359.—Preliminary note on the action of alkyl iodides on silver malate, by T. Purdie and G. D. Landor. A mixture of isopropylic isopropoxysuccinate and isopropylic malate is obtained by the action of isopropylic iodide on silver malate; the formation of the first compound suggested the idea that the alkylic malates produced from the silver salt may be contaminated with alkyloxysuccinates. This idea seems to be fully confirmed by examination of the alkylic malates so obtained.—On certain thiocarbimides derived from complex fatty acids, by A. E. Dixon.

Entomological Society, November 18.—Prof. Raphael Meldola, F.R.S., President, in the chair.—Mr. Tutt exhibited a series of the ochreous form of *Tephrosia bistortata*, Goetze, known as ab. *abietaria*, Haw., captured by Mr. Mason in March 1895 and 1896, near Clevedon, Somerset; also a series of the second brood of the same species (ab. *consonari*, St.), bred from ova laid by the Clevedon specimens. He also exhibited a series of *Tephrosia crepuscularia*, Hb. (*biundularia*, Esp.), taken by Dr. H. Corbett at Doncaster; a peculiar variety of *Hipparchia semele*, captured by Mr. H. S. Clarke near Ramsey, Isle of Man; also a series of *Plusia bractea* bred from ova laid in July last. The eggs and larvæ had been subjected to forcing treatment, with the result that the moths emerged in October.—Dr. Sharp called attention to Mr. Ernest Green's plates of the *Coccidæ* of Ceylon, which were exhibited on a screen in the room, and said that he had been inclined to consider the *Coccidæ* as a distinct order of insects, but at present the evidence was hardly sufficient to warrant this. He asked Mr. Green if he could give him any information with regard to the development of the wings in the male. Mr. Green said that in the males of the *Coccidæ* the wings first appeared in the penultimate stage as small projections on the sides of the thorax. These wing-pads grew to a certain extent without any further ecdysis. Though the insect was then quite inactive, and took no food during this stage, the rudimentary wings and legs were free from the body, and were capable of some slight movement. After the final ecdysis the wings of the imago were fully expanded, and assumed their natural position before the insect left the sac, or puparium, in which the resting stage had been passed.—Mr. Bethune-Baker exhibited a yellow spider from Orotava, which was of the exact colour of the flowers that it usually rested upon, and which had been observed to catch *Vanessæ* which settled on these flowers. Mr. Barrett said he had noticed a spider with the same habit on the ox-eye daisy in Surrey. Mr. Bethune-Baker also exhibited a very curious dark variety of *Arctia caja*, bred by Mr. Moore.—Prof. Meldola stated that it had been of late found difficult to store bristles in the city owing to the ravages of a moth, living specimens of the larvæ and pupæ of which he exhibited. Mr. Barrett said that the moth was *Tinea biselliella*. Mr. Bland did stated that the bisulphide of carbon treatment might be found to be of advantage if it were practicable, but more would have to be ascertained with regard to the extent and character of the ravages before anything could be determined upon. Mr. Merrifield, Mr. Green, and others took part in the discussion which followed.—Mr. Blandford called attention to the use of formalin as a preventive of mould, and said that it would probably be found of use in insect collections; an object once sprayed with this substance never became mouldy afterwards. Prof. Meldola said that formalin was another name for a solution of formic aldehyde; it is now much used in the colour industry, and is, therefore, produced on a large scale.—Mr. Newstead communicated a paper entitled "New *Coccidæ* collected by the Rev. A. E. Eaton in Algeria."

Zoological Society, November 17.—Dr. St. George Mivart, F.R.S., Vice-President, in the chair.—Mr. Sclater gave an account of some of the more interesting animals observed by him during a visit to the Gardens of Antwerp, Cologne, Dusseldorf, Hanover, Amsterdam, the Hague, and Rotterdam in June last.—Mr. P. Chalmers Mitchell made remarks on a supposed case of telegony exhibited by a fox-terrier in showing peculiarities due to a previous fertilisation of its mother by a Dachshund. A discussion followed, in which Sir Everett Millais, Mr. Tegetmeier, and others took part, and

expressed opinions generally unfavourable to the theory of telegony.—Dr. Leonard Hill made some remarks on supposed cases of the inheritance of acquired characters as shown by breeding guinea-pigs.—Mr. Sclater exhibited, on behalf of the Hon. H. S. Littleton, a coloured life-sized model of the Australian lung-fish (*Ceratodus forsteri*).—Mr. Blanford, F.R.S., exhibited, on behalf of Major C. S. Cumberland, some heads of *Ovis ammon* shot by him on the Altai Mountains in Central Asia.—Mr. Oldfield Thomas read a paper "On Further Collections from Nyasaland," being a continuation of three previous papers on the mammals of that country. The specimens now referred to had been collected and sent home by Sir Harry Johnston, Consul Alfred Sharpe, Dr. Percy Kendall, and Mr. Alexander Whyte. Two species were described as new: a peculiar hoary-coloured baboon from Fort Johnston, proposed to be called *Papio pruinosus*, and a steinbok with the white streaks in its fur characteristic of the grysbok. The latter had been obtained by Mr. Sharpe in Southern Angoniland, and was proposed to be called *Raphiceros sharpei*.—Mr. W. E. de Winton read a paper on some rodents from Mashonaland and Matabeleland, British South Africa, collected by Mr. J. Ffolliott Darling and Mr. F. C. Selous. This memoir contained descriptions of six species and two subspecies of rodents new to science. Amongst these were a dormouse very much smaller than *Graphiurus murinus*, to which the name *G. nanus* was given; a pouched rat, which was called *Saccostomus mashonæ*; and a mole-rat, proposed to be called *Georychus nimrodi*.—A communication was read from Mr. Alfred E. Pease containing notes on the antelopes of the Aures and Eastern Algerian Sahara.—Communications were read from Dr. A. G. Butler, on two collections of Lepidoptera made by Mr. R. Crawshay in Nyasaland; and on a collection of Lepidoptera from Nyasaland, presented to the Museum by Sir H. H. Johnston, K.C.B., and collected by J. B. Yule.—A communication was read from Mr. Joseph I. S. Whitaker, containing field-notes on the gazelles of Tunisia.

Anthropological Institute, November 24.—Mr. E. W. Brabrook, President, in the chair.—Lieut. Boyle T. Somerville, R.N., read a paper entitled "Ethnographical Notes on New Georgia, Solomon Islands." Lieut. Somerville recently passed some time in the islands while on surveying duty with H.M.S. *Penguin*, and both he and Lieut. Weigall acquired sufficient knowledge of the native dialects to be enabled to converse with the people in their own language. To this circumstance, and to the fact that the hints given in "Anthropological Notes and Queries" were systematically followed, a paper of quite exceptional interest was due, which forms a valuable addition to previously existing material on the ethnology of the South Seas. A point of exceptional importance is the occurrence of a rarely seen hairy animal in the jungles in the interior of the island. From the descriptions given by a number of natives, of which Lieut. Somerville quoted five of independent origin, this animal would appear to resemble an anthropoid ape, though a native who had seen one declared that it was not very like a monkey shown to him on board a European ship. The peculiar prognathous character of the well-known carved figures made in the Solomon Islands is possibly copied from a similar characteristic noticed in an animal prototype. Whatever this animal may be, the natives here canonised it as an evil spirit, and attribute to it the power of visiting either with sickness or death those who are unfortunate enough to see it. In spite of these fanciful beliefs, the positive existence of some such animal is confirmed by Lieut. Weigall, who himself saw a curious hairy animal on the edge of the jungle, but was unable to approach within sufficient distance to obtain a perfectly clear view. It must be remembered that the vegetation in this part of the Pacific is unusually dense, owing to the very frequent and regular rainfall. Nearly all the natives live close to the sea, and in order to penetrate into the interior it is necessary literally to cut one's way. Under these circumstances it is at least possible that some rare species may have hitherto evaded the notice of travellers. Lieut. Somerville believes this to be the case, and he is a competent observer, quite able to estimate the value of the evidence presented in the different native accounts. A number of admirable lantern-slides accompanied the paper, and specimens of native art in the form of pencil-sketches of the frigate-bird, canoes, &c., made by natives under the author's eye, were exhibited. A carefully copied specimen of native music was also shown.

MANCHESTER.

Literary and Philosophical Society, December 1.—Dr. Edward Schunck, F.R.S., President, in the chair.—The President exhibited some specimens of the cochineal insect, and of the Cactus *Opuntia*, the only member of the Cactaceæ on which the insect lives.—Dr. C. H. Lees called attention to the experiments of E. Wiedemann on the specific heats of vapours and their variation with temperature, and remarked that, since the specific heats of all the vapours experimented on increase with the temperature, it is probable that they do so for all vapours, including steam. Hence, the value of the specific heat of steam between given temperatures, required in Rankine's formula for the total heat necessary to raise water from any temperature to steam gas at another temperature, is still unknown.—Descriptions of new species of mollusca from the millstone grit, and lower coal measures, of Lancashire, by H. Bolton. The author described five species of mollusca and one brachiopod from the millstone grit and lower coal measures which have recently come into the possession of the Manchester Museum, Owens College, by the acquirement of the collections of Sir U. Kay-Shuttleworth, Geo. Wild, and R. W. Cairns. Of the mollusca, three belong to the Pelecypoda, and two to the Gastropoda. Two of these are altogether new to the coal measures, and one proves to be of considerable importance to miners, as it occurs, in all cases yet known, immediately over the valuable Cannel Mine of the middle coal measures. The brachiopod is interesting in that it occurs in the lower coal measures and, also, in a remarkable marine band of the middle coal measures at Ashton-under-Lyne, the two horizons being separated by nearly 2000 feet of rock matter.—On some errors in science, by C. L. Barnes.

PARIS.

Academy of Sciences, November 30.—M. A. Cornu in the chair.—On periodic solutions and the principle of least action, by M. H. Poincaré.—Scientific exploration by balloon, by M. Mascart. Simultaneous experiments were carried out with captive balloons at Berlin, Munich, Varsovie and St. Petersburg, and with free balloons at Paris, Berlin, Strasburg and St. Petersburg, for the purpose of carrying out meteorological observations. The highest altitude was reached by the Paris balloon, 15,000 metres, the temperature indicated being −60° C. Each ascent will be described later in full detail.—Estimation of nitric acid in the waters of the Seine, Yonne, and Marne, during the late rise, by M. Th. Schlœsing. The results obtained show that great rises in autumn contain much more nitrates than those at the end of the winter.—The lymphatics of the intestinal villosity in the rat and rabbit, by M. L. Ranvier.—On the periodic Giacobini comet, by M. Perrotin. A new system of elements for the Giacobini comet, from observations made at Nice between September 4 and November 3, 1896.—Actinometric observations made on Mount Blanc, by MM. Crova and Houdaille. From observations at Grands-Mulets (3020 metres), a value of 2·9 calories is deduced for the solar constant.—Remarks by M. Appell on the presentation of the second volume of his work on elliptic functions.—Reclamation of priority, by M. Stuart-Menteath, concerning his work on the geological constitution of the Pyrenees.—On the singularities of linear partial differential equations of the first order, by M. F. Marotte.—On a remarkable displacement, by M. Raoul Bricard.—On molecular entropy, by M. Georges Darzens. The product of the usual expression for the entropy of unit mass by the molecular weight of the substance, is called the molecular entropy. It is shown that for all bodies possessing similar molecular constitutions, compared in corresponding states, the difference of molecular entropy between two given states is the same.—On the absorption of nitric oxide by ferrous bromide, by M. V. Thomas. In aqueous solution at 10°, the absorption corresponded to the formation of the compound $3FeBr_2.4NO$, at temperatures higher than this (15°–16°), the results indicated the formation of $Fe_2Br_4.NO$.—On the tempering of steel in phenol, by M. Levat. Comparative trials on the same steels tempered in water and phenol respectively, showed the hardness and elasticity in the latter case was much greater than in the former.—Action of potassium permanganate upon polyhydric alcohols and their derivatives, by M. L. Perdrix. Carbon dioxide, formic acid, and water are the only products.—Action of ammonium nitrate upon *Aspergillus niger*, by M. C. Tanret. An excess of ammonium nitrate in a solution in which *Aspergillus* is growing, tends to retard or even to prevent the formation of

spores, the mycelium remaining white. At the same time that the *Aspergillus* is forced to grow by mycelium, free nitric acid appears in the cultivating liquid, and starch is formed in the tissue of the fungus.—Application of the Röntgen rays to the study of the skeletons of animals not extinct, by M. V. Lemoine. —The bacteria of coal, by M. B. Renault. A study of the fossil bacteria in coal. Two varieties of a species, named *Micrococcus carbo*, are described, together with a bacillus to which the name *Bacillus carbo* is given.—Minerals formed from lead scoriæ from Laurium, by M. A. Lacroix. The lead mines at Laurium (Greece), worked by the Athenians for lead and silver, gave rise to scoriæ rich in lead and unreduced galena. The sea-water, acting upon these scoriæ for more than two thousand years, has given rise to numerous crystallised minerals, among which were recognised laurionite, penfieldite, fiedlerite, phosgenite, cerussite, anglesite, matlockite, and hydrocerussite. —On the lower Cretaceous beds in valley of Oued Cherí, by M. J. Blazac.—On the ascent of the captive balloon at Paris on November 14, 1896, by MM. G. Hermite and G. Besançon.—Additional note to a preceding communication, on the relations existing between the lunar movements and barometric changes, by M. A. Poincaré.—On a new practical method of preparing acetylene, by M. L. Lechappe.—The microphone and the discovery of springs, by M. L. Holtz.—Nervopsychosis, by M. Boukteieff.

DIARY OF SOCIETIES.

THURSDAY, DECEMBER 10.

ROYAL SOCIETY, at 4.30.—On Prof. Hermann's Theory of the Capillary Electrometer: G. J. Burch.—An Attempt to determine the Adiabatic Relations of Ethyl Oxide: E. P. Perman, Prof. Ramsay, F.R.S., and J. Rose-Innes.—The Chemical and Physiological Reactions of certain Synthesised Proteid-like Substances: J. W. Pickering.—An Experimental Examination into the Growth of the Blastoderm of the Chick: R. Assheton.

MATHEMATICAL SOCIETY, at 8.—A Discovery in the Theory of Compound Denumeration: Prof. Sylvester, F.R.S.—On the Stationary Motion of a System of Equal Elastic Spheres of Finite Diameter: S. H. Burbury, F.R.S.—Concerning the Abstract Groups of Order $K!$ and $\frac{1}{2}K!$ Holoedrically Isomorphic with the Symmetric and the Alternating Substitution Groups on K Letters: Prof. E. H. Moore.—On the Influence of Viscosity on Waves and Currents: S. S. Hough.—On a Series of Co-trinodal Quartics: H. M. Taylor and W. H. Blythe.—The Connection of Quadratic Forms: Lieut.-Colonel Cunningham, R.E.—Description of Mr. Macfarlane Gray's Multiplying Apparatus: T. I. Dewar and Prof. Greenhill, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Annual General Meeting.

SOUTH LONDON ENTOMOLOGICAL AND NATURAL HISTORY SOCIETY, at 8.—Notes on the North American Agrotis subgothica: W. Mansbridge.

FRIDAY, DECEMBER 11.

PHYSICAL SOCIETY, at 5.—The Application of Physics and Mathematics to Seismology: Dr. C. Chree.—On Musical Tubes: R. J. Rudd.

ROYAL ASTRONOMICAL SOCIETY, at 8.—Report on the Expedition to Japan to observe the Total Solar Eclipse of 1896, August 9: W. H. M. Christie, Captain E. H. Hills, and H. H. Turner.—Report on the Expedition to Norway to observe the Total Solar Eclipse of 1896, August 9: A. A. Common.—Real Paths of 101 Meteors observed during the Ten Years ending November 1896: W. F. Denning.—Catalogue of Real Paths of Large Meteors: G. von Niessl.—Ephemeris for Physical Observations of the Moon, 1897: A. Marth.—The Theory of New Stars: W. E. Wilson.—Observations of Minor Planets at Windsor, New South Wales: John Tebbutt.—Comparison of the Sun's Longitudes for 1901, computed from Newcomb's Tables of the Sun, with those computed from Le Verrier's Tables: A. M. W. Downing.—Approximate Ephemerides of the Leonids for the First Four Months of 1897: G. Johnstone Stoney.

SATURDAY, DECEMBER 12.

ESSEX FIELD CLUB (at Chingford), at 7.—Note on the Discovery of the Male of Prestwichia aquatica in Epping Forest: F. Enock.—The Federation Ideal for Natural History Societies, with special reference to the Eastern Counties: G. S. Boulger.—On the Diffusion and Local Extinction of Molluscs: J. French.

TUESDAY, DECEMBER 15.

ZOOLOGICAL SOCIETY, at 8.30.—Contributions to our Knowledge of the Plankton of the Faëroe Channel: Dr. G. Herbert Fowler.—On the Genera of Rodents; an Attempt to bring up to Date the Current Arrangement of the Order: Oldfield Thomas.—On Lysechinus, a New Genus of Plesiocidaroids from the Tyrolese Trias: Dr. J. W. Gregory.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Papers to be further discussed: Tipping and Screening Coal: James Rigg.—The Surface Plant at Kirkby Colliery: Thos. Gillott.—Paper to be read, time permitting: Steel Skeleton Construction in Chicago: E. C. Shankland.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.—Some Probable Causes of Trouble in Photo-engraving, with Demonstrations of Methods for their Detection: Andrew Wybrandt-Penrose.

WEDNESDAY, DECEMBER 16.

GEOLOGICAL SOCIETY, at 8.—On the Subdivisions of the Carboniferous Series in Great Britain, and the True Position of the Beds mapped as the Yoredale Series: Dr. Wheelton Hind.—Note on Volcanic Bombs in the Schalsteins of Nassau: Prof. E. Kayser.

ROYAL METEOROLOGICAL SOCIETY, at 7.30.—An Attempt to Determine Velocity Equivalents of Wind-Forces estimated by Beaufort's Scale: Richard H. Curtis.—The Winter Climate of Egypt: Dr. H. E. Leigh Canney.

ROYAL MICROSCOPICAL SOCIETY, at 8.

THURSDAY, DECEMBER 17.

ROYAL SOCIETY, at 4.30.

LINNEAN SOCIETY, at 8.—On the Chalcididæ of the Island of Grenada: Dr. L. O. Howard.—On the Development of the Ovule of Christisonia, a Genus of the Orobanchæ: W. C. Worsdell.

CHEMICAL SOCIETY, at 8.—On the Experimental Methods employed in the Examination of the Products of Starch-hydrolysis; on the Specific Rotation of Maltose and of Soluble Starch; on the Relation of the Specific Rotatory and Cupric-reducing Powers of Starch-hydrolysis by Diastase: Horace T. Brown, F.R.S., Dr. G. H. Morris, and W. H. Millar.

ROYAL STATISTICAL SOCIETY, at 5.30.

FRIDAY, DECEMBER 18.

EPIDEMIOLOGICAL SOCIETY, at 8.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Wells, and Well-sinking: John W. Kitchen.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—The Story of the Chemical Elements: M. M. P. Muir (Newnes).—The Parasitic Diseases of Poultry; F. V. Theobald (Gurney).—The Story of our Planet: Prof. T. G. Bonney, cheap edition (Cassell). List of the Vertebrated Animals now or lately living in the Gardens of the Zoological Society of London, 9th edition (Longmans).—The Plant-Lore and Garden-Craft of Shakespeare: H. N. Ellacombe, new edition (Arnold).—The Natural History of the Marketable Fishes of the British Islands: J. T. Cunningham (Macmillan).—The Tutorial Chemistry. Part II. Non-Metals: Dr. G. H. Bailey (Clive).—Report on the Work of the Horn Scientific Expedition to Central Australia, Part I and Part 4 (Dulau).—Charles Darwin and the Theory of Natural Selection: Prof. E. B. Poulton (Cassell).—Annuaire pour l'an 1897, publie par Le Bureau des Longitudes (Paris, Gauthier-Villars).—Catalogue of the Michigan Mining School, 1894-96 (Houghton, Michigan).—Zoological Record, 1895; edited by D. Sharp (Gurney).—Le Déterminisme Biologique et la Personnalité Conciente: Dr. F. Le Dantec (Paris, Alcan).—Grasses of North America: Dr. W. J. Beal, Vol. 2 (New York, Holt).

SIR GEORGE AIRY.

Autobiography of Sir George Biddell Airy, Honorary Fellow of Trinity College, Cambridge, Astronomer Royal from 1836-1881. Edited by Wilfrid Airy, B.A., M.Inst.C.E. (Cambridge: University Press, 1896.)

DE MORGAN, in a letter to Dr. Hamilton, has humorously described one of the most salient features of Airy's character. "Airy," he wrote, "is the prince of methodists. My theory is that when he tries his pen on blotting-paper, he makes a duplicate by the pressing machine, files, and indexes it." This is scarcely an exaggeration, and suggests that every line that Airy wrote, however trivial, found an assigned place in the Greenwich archives. Scarcely any one could have left fuller materials from which a biography could have been constructed; while the genius of order and arrangement that pervaded Airy's life, must have made the task of compilation comparatively simple. The editor tells us that this love of order outlived capacity itself, and that at the close of his life he occasionally exhibited more anxiety to have a letter placed in its proper pigeon-hole, than even to master its contents. In addition to this mass of information which Airy had stored up, he had also written a series of skeleton annals of the Observatory, which, he remarks, unavoidably partook in some measure of the form of biography. It is from these skeleton notes, existing in manuscript, that his eldest surviving son has prepared the present biography. The editor, in the use he has made of this information, has had evidently but one wish—that of placing before the world the public life of a celebrated man, to whom this country is much indebted for hard and conscientious work, and along lines which sometimes lay utterly outside his official duties. Mr. Wilfrid Airy is content to be merely a commentator, to keep in the background, and to let Sir George tell his own tale. The result of this devotion to the memory of his father, is to exhibit everywhere in the clearest possible manner what Airy did, and to what extent he can command our gratitude; but it prevents the introduction of any great amount of new or interesting information, which the less public portion of his papers might have disclosed, and to a knowledge of which the public might be permitted.

The plan of the book is arranged to give a strictly chronological account of Airy's life, and indeed, after Airy came prominently before the public, each year is separately treated. Seeing that the history of the National Observatory for forty-five years is the history of Airy's life, the main contents of these yearly accounts are supplied either by copious extracts from, or abridgements of, the Annual Reports of the Astronomer Royal to the Board of Visitors. These extracts are supplemented by references to other work in which Airy was interested, but of which no mention to the Board of Visitors was necessary. At the end of each yearly summary, a few remarks on private history are added; but these generally contain little more than the dates for which he had leave of absence, and the mention of the places visited on those occasions. Sometimes a letter to or from private friends is added, and every one will regret that more examples of his correspondence could not be given. But in justice to the editor, it must be borne in mind that, if the book is to be kept within ordinary bounds, it is not possible to allow more than five or six pages to each year so treated, a space that does not permit many extracts from private letters. No doubt the editor regrets that he has been compelled to suppress so much that would have added to the interest of the book.

In the first chapter is given a personal sketch of the subject of the memoir, dealing with his habits and amusements, and necessarily offering some estimate of his character. In one or two particulars this is, perhaps, written rather too modestly. For instance, there is very little allusion to Airy's classical attainments, on which, on more than one occasion, the writer of this notice has had reason to remark that Airy prided himself. Moreover, that Airy laid great stress on the importance of a classical education is shown by his references, in the earlier part of the autobiography, to the authors that he read, and his strict adherence to the practice of writing some Latin prose every day. In 1824, he conceived the idea of competing for the Middle Bachelor's Prize, and began a Latin essay with that view. This he abandoned with regret, not from the hopelessness of the competition, but from want of leisure.

In the second chapter, and generally throughout the book, Airy speaks for himself in the first person. Here he gives an interesting description of the life of a Sizar at Cambridge some eighty years ago. It is curious and instructive to follow Airy's life at this time, ridiculed for his strict adherence to the prescribed costume of drab knee-breeches, dining off the fragments of the Fellows dinner, brought to him on pewter plates, declaiming in chapel, and the undergraduates attempting to cough him down because he was long in preaching. The contentment with which Airy went through this portion of his life, the pleasure with which he looks back to his quiet rooms in Neville's Court, almost the worst in the college, his continual success in his many examinations, all offer pictures which we cannot afford to lose, and will be read with a certain charm by those who knew him in his later days. Airy retained for his University a profound affection throughout his life, an affection which, among other ways, evidenced itself in the continual struggle which he waged in after years with the examiners, in his attempts to place the examinations on a footing that he held to be best suited for undergraduate education. The correspondence which Airy had with Prof. Cayley and others on this subject is specially interesting as offering a conspicuous example of Airy's power of controversy, a power which many must have had reason to remember. We have no intention of criticising the position which Airy supported, a position which was perhaps inevitable, considering his own University career and early training, both of which he found admirably adapted to his after-official life. This life possibly prevented him from fully appreciating the educational value of a mathematical training, marvellously widened and extended as it had

been since he left the University. It will generally be felt that it was fortunate for Cambridge life and mathematical advancement that the views that he urged were not generally admitted by those responsible for the scheme of instruction and education.

It is unnecessary to recall here the principal events of Airy's scientific career. So many accounts were written shortly after his death by those well qualified to speak, that his indefatigable work and the honours that he earned are comparatively fresh in our memories. But there have been moments of unusual interest in his busy life, when his conduct has been somewhat rudely assailed, and his judgment questioned by his contemporaries. One would like to know what Airy thought of these attacks, and whether he attempted to justify himself to his own mind. So far as this autobiography goes, there is no evidence that he was ever elated by well-merited success, or depressed by captious criticism. He never makes any attempt to defend himself or to blame others. The path of duty, as he conceived it, is manfully pursued with firmness and decision. His confident reliance on his own judgment seems never for a moment to desert him. As an illustration, one may quote his reference to the discovery of Neptune. In the whole history of astronomy, there is no subject about which a keener interest is felt, by amateurs especially, than in the Adams and Le Verrier controversy, and the part played by the more conspicuous actors in that history. Few, possibly, have read the whole correspondence, and fewer still, probably, are qualified to give a right judgment on all the facts; but this does not prevent warm partisanship and a determined effort to find a scapegoat, on whom they can vent their spleen and ill-temper. And if this is still the case after fifty years, one can imagine what were the excitement and the disappointment at the time of discovery. Here is the last place in which Airy can say how he was affected by the uproar, and also to add anything to the history of the epoch. Practically he says nothing. He contents himself by referring to his official communications to the Royal Astronomical Society, and adding, "I was abused most savagely both by English and French," but there is not one word to hint that he ever thought he could have acted differently, or that the course he pursued was not the only one practicable. His equanimity is apparently quite undisturbed. Similarly, in 1847, when Airy endeavoured to persuade the Royal Astronomical Society to so alter the bye-laws as to permit a medal to be given to both Adams and Le Verrier, and his proposal was defeated after two days' stormy discussion, there is no evidence to show that he blames those who prevented this act of tardy justice, or that he considered their judgment was warped by unworthy motives. The attacks made across the Council table on that occasion were certainly bitter, and in some cases unwarrantable; but on Airy they seem to have left no permanent impression, or at least so slight that he does not care to chronicle it.

But that Airy could feel acutely and rebuke severely is quite sufficiently testified by his conduct towards Sir James South and General Sabine. These two names have been frequently quoted as illustrative of the bitterness of Airy's animosity. But it must be remembered that both these opponents called in question his conduct as Director of the Observatory, and it is possible that he felt more keenly attacks directed against the institution than against himself personally. From the former it will be admitted that Airy had ample provocation. South had attacked him in the House of Commons through Sir Robert Inglis, questioning almost everything that Airy had done in the Observatory, and later had lodged a formal complaint at the Admiralty that Airy did not personally observe with the instruments in his charge. Sir James was worsted on both occasions; but in his reference to them, Airy does not exhibit any rancour, or think it necessary to add anything to the defence made at the time of the accusation. For him the incident is closed, and he refers to it as impersonally as to any other piece of history. General Sabine had implied mistrust of the magnetical observations, and after an acrimonious correspondence, Airy distinctly intimated that he could no longer act in confidence with Sabine as a member of the Board of Visitors. There the incident closed, and the dispute probably went no further than concerned the special matter in question; for Airy subsequently makes a not unkindly reference to Sabine's general powers as a mathematician and investigator.

It has been said of Airy that he was a man who never made a friend, and this has been adduced as a proof of the moroseness or the self-sufficiency of his character. The editor seems to have had some such remark in his mind, and at the conclusion of what may be called the first part of Airy's life—namely, the exchange of Cambridge for Greenwich—he inserts some remarks on the friends with whom Airy was intimate, and with whom he maintained constant intercourse till their death. As these friends were all older than Airy, they all predeceased him, and one can understand that there is no similar reference to friends that he made at Greenwich, when he left the Observatory for the White House. A man who had enjoyed the intimacy of Whewell and of Sedgwick, of Sheepshanks and of Peacock, may have found it difficult to fill their places, and with him memory may have satisfied the want that social intercourse meets in other men. Moreover, he was singularly happy in his family relations. Other writers have told us what Airy did in scientific work; this book tells us something of his private life, and exhibits him as a most affectionate husband and devoted father. His wife, to whom he proposed marriage two days after his introduction, a mark of precipitancy that one would have scarcely anticipated in the late Astronomer Royal, "was by natural ability and education well qualified to enter into the pursuits of her husband, and in many cases to assist him." In one place, Sir George Airy tells us that the best diagrams with which he illustrated his lectures were painted by his wife. His solicitude to make her participate in the pleasures he derived from his short journeys, by writing to her daily while he was absent, speaks much for his affectionate disposition. Those who have known Airy only in his official relations, will find much in this book to make them review the estimate they may have formed of his character.

W. E. P.

A NEW WORK ON CYTOLOGY.

Die Morphologie u. Physiologie des Pflanzlichen Zellkernes. Eine kritische Litteraturstudie. Von Prof. Dr. A. Zimmermann. Pp. 188. (Jena: Gustav Fischer, 1896.)

IF it be true that the growth of a science is to be estimated by the degree of division of labour which it exhibits, botanists have every reason to regard the work of the last fifteen years with no small degree of satisfaction. For the incessant investigations in every department of plant-life have been so vigorously prosecuted, that it has become utterly impossible for any simple mind to grasp the details of the various ramifications of the subject as it exists at the present day. At the same time, it is essential for any one who desires to avoid the evil results of exclusive devotion to one branch of the science, that he shall be in a position to appreciate the general nature of the results which are being arrived at in other fields of inquiry.

Now it can hardly be denied that at present the why and the wherefore of the phenomena exhibited by living bodies is the theme which is attracting, perhaps, the widest share of interest on the part of the botanist and zoologist alike; and the generalisations accruing from investigations of matters germane to these problems, possess a significance hardly less weighty for others who, though not strictly speaking biologists, are yet seeking to penetrate the mysteries embodied in the terms life and organisation.

And although we are accustomed to hear hypotheses confidently advanced and views dogmatically urged in connection with these and kindred matters, it is surprising to discover how small a substratum of solid fact we have as yet secured wherewith to lay the foundations for our many and elaborate theories. Thus the philosopher speculates on the origin and nature of consciousness, too often without possessing the faintest conception of the anatomy and physiology of the brain; writers on heredity are too prone to generalise from a scanty range of empirical facts, the mutual relations of which are still at best but obscure. And yet it is only by carefully collecting and collating the facts, that they can be made to tell their own story; and seeing that the aims both of biology and of philosophy are at bottom the same, namely to explain as far as may be the phenomena of life, it is surely not too much to expect that the living substance, the protoplasm, should form a prime object of earnest research. We are fairly well acquainted with the rough and ready ways in which organisms adapt themselves to their surroundings; we possess some knowledge as to the chemical processes which are inseparably associated with the exercise of vital activity; but of the mechanism itself, of the essential machinery, we know next to nothing at all, and the isolated facts which have as yet been gleaned respecting it often appear so conflicting that we might almost despair of ever getting really at close quarters with the object of our quest at all.

It is in the hope that this point of attack may prove to be not altogether impregnable, that such considerable efforts are being now concentrated on the details of cell structure. And we have made certain advances in this direction. We know that the essential feature of the sexual process lies in the fusion of two cells; we know that these cells have passed through antecedent changes very dissimilar from those which characterised the ordinary cells constituting the body or *soma* of the organism. What as yet we do *not* know is how to arrange our newly acquired facts in proper perspective; that knowledge can only be attained when our range of available fact is far greater than is at present the case. But the obstacles which beset the investigator in this difficult path are so many, that it may even take years to unravel the sequence of events in a single nuclear division. Nevertheless it is certain that the time so spent is not wasted, for it is only when we shall have arrived at such a position as will enable us to compare a large number of carefully and accurately ascertained facts that we can reasonably expect to apply our knowledge to the effective storming of some, at least, of the outworks of the citadel in which nature's secrets are so jealously guarded.

Dr. Zimmermann has rendered no small service to those who desire to do something in the field of cytological inquiry. He has carefully and impartially (perhaps too impartially) summarised the results of nearly all the recent advances in this branch of botany, and thus his book forms a handy work of reference to the extensive literature which is so rapidly growing up on these matters.

But the reader must not expect to meet with a critical and synthetic discussion of the results which have been obtained. He is left, for the most part, to form his own conclusions as best he can; and perhaps we may be pardoned for wishing that Prof. Zimmermann had seen his way to give a little more definite expression to his own views, especially as he is himself well known as an investigator in these matters. For example, on page 59 there is figured a dividing nucleus of *Lilium Martagon*, after Guignard, in which prominent centrospheres are represented as occupying the poles of the spindle. But in all the figures of the *same plant* taken from the author's own works, the centrospheres are omitted; and yet in one passage only (so far as we have seen) is any doubt tentatively cast on the accuracy of the statements alleging the existence of centrospheres in the lily. We think definite plain statements in a case like this would have been more useful than a cautious expression of doubts which have been growing up for a long time respecting the instance just cited. At any rate, such a course would have raised the question. It must be faced sooner or later, and the sooner it is raised—and finally answered—the better.

The book is divided into three main parts, the first dealing with technique, and with the chemistry and physiology of the nucleus in general. The second part of the work is devoted to a consideration of the structure and behaviour of this body in the different groups of the vegetable kingdom, and a good deal of useful information respecting fertilisation and embryology is here brought together. The third part consists of a copious and most useful bibliography, which will be welcome to every one who wishes to obtain a more thorough knowledge of the subject.

Dr. Zimmermann naturally could not profitably discuss

the questions suggested by a study of the literature here abstracted without due reference to the work accomplished by the zoologists in the same field. But, in his preface, he has expressly signified his intention of confining himself in the main to the phenomena exhibited by plants; and so, however much we may regret the results of this self-denial, we cannot but admit that the author has acted wisely in refraining from drawing general conclusions which must have been one-sided, and proportionally futile. As it is, although we cannot exactly say his book is very readable, it is at any rate a useful one, and should be certain of receiving a favourable reception at the hands of those whose business or pleasure impels them to keep abreast with current investigations in this department of science.

J. B. F.

COLLIERY MANAGEMENT.

Colliery Working and Management. By H. F. Bulman and R. A. S. Redmayne. Pp. xvi + 330. (London: Crosby Lockwood and Son, 1896.)

THREE hundred and forty years ago the learned German writer Agricola, enumerated, in the first book of his treatise, *De re metallica*, the various branches of knowledge that ought to be acquired by a mine manager. First he should be familiar with chemistry, geology, mineralogy and other branches of philosophy; secondly with medicine, that he may cope with the diseases and accidents to which miners are liable; thirdly with astronomy, that he may carry out scientific surveys; fourthly with geometry, that he may prepare underground plans and sections; next with arithmetic, that he may keep account of the mining costs; then with engineering, that he may construct machinery and buildings; also with drawing and colouring, that he may execute designs; and lastly with mining law, that he may avoid difficulties with others, and prevent his neighbours from taking advantage of him. Much more difficult are the problems with which the colliery managers of to-day have to deal. They have to extract coal from great depths, and to labour under stringent legislative enactments. In short, in the words of Mr. T. Forster Brown, the ideal colliery manager ought to be a scientific philosopher with a thoroughly practical knowledge of mining, of men, and of applied mechanics. The successful execution of the duties of a colliery manager implies the getting of the largest possible proportion of the workable coal in the best condition at the lowest possible cost, and with the greatest degree of safety to the miners. It is remarkable, therefore, that the methods of working the coal, and the arrangement and supervision of the labour employed, have received but slight consideration in the literature of coal-mining. This is due to the fact that Mr. H. W. Hughes' recently published text-book of coal-mining and the older treatises on the subject deal rather with mine engineering than with colliery working; and owing to the vast amount of matter to be dealt with, subjects relating to labour, wages, cost of working and systems of getting the coal, have to be crowded into one or two chapters. Mr. Bulman and Mr. Redmayne, who are both experienced colliery managers of great literary ability, are therefore to be congratulated on having supplied an authoritative work dealing with a side of the subject which has hitherto received but scant treatment.

The authors break up their book into fourteen chapters In the first three chapters they deal historically with the progress achieved during the last few centuries in the methods of working coal, in working costs, and in conditions of labour. In the succeeding five chapters they describe the duties and qualifications of a colliery manager and of the various grades of subordinate officials, the superintendence of labour, the arrangement of labour and the system of wages, wages bills and cost-sheets, and the tools and appliances used by the workmen. In the concluding six chapters they discuss in practical detail the different systems of working coal, namely the bord and pillar, the longwall, and the double and single stall methods, and the modifications requisite for working two seams near together. Lastly in an appendix covering seventy-five pages, they give the text of various documents illustrating the past history or the present condition of coal-mining, including a statement of the comparative cost of working bord and pillar and longwall, the official abstract of the Coal Mines Regulation Act 1887, the special rules established under that Act, pitmen's yearly bonds in 1767, 1779 and 1859, forms of hiring agreements, forms of rules regarding the drawing of lots to determine working places, joint-committee rules, and the text of the Coal Mines Regulation Act 1896, and of the Truck Act 1896. The volume concludes with a glossary of mining terms and an excellent index.

From this summary of the contents, it will be seen that the arrangement of the matter has been well thought out, and that the volume is an addition of permanent value to mining literature. The book is, however, open to one grave objection. It is too local in character; almost all the examples being selected from Northumberland and Durham, the district with which the authors are most familiar. Even when they describe the longwall method of working, they choose their instances from the North of England coalfield. The longwall system of that coalfield, however, differs considerably from that of the Midlands, where the method originated, and where it is carried out to perfection. This difference is due to the fact that the conditions of labour are not the same in the two coalfields. In the North, each man works for himself; whilst in the Midlands sets of men work together, the result being that in the former district longwall consists of short faces or stalls, whilst in the latter the stalls are from thirty to fifty yards long, and continuous instead of being a series of broken steps. In fact, longwall in the North can rarely be regarded as longwall proper, but would be better described as a longwall modification of the bord and pillar method.

The local character of the work is also apparent in the technical terms employed. The pages are freely sprinkled with such words as *cavils*, *cracket*, *dillies*, *jenkin*, *keeker*, *kist*, *ramble*, *stook*, *wailing*, &c. Outside the North of England coalfield these terms are not understood, and constant reference to the glossary is absolutely necessary. This indiscriminate use of local slang is greatly to be regretted as tending to limit the

book's field of usefulness. It might easily have been avoided, for Prof. Le Neve Foster has shown in his mining works that it is quite possible to replace provincialisms by words that are generally understood among English-speaking nations.

The authors elucidate their text by 119 woodcuts and 28 plates, most of which are admirable reproductions of photographs taken underground with the aid of the magnesium flash-light. These illustrations are excellent. The only exception that can possibly be taken to them is that several of them are unnecessary. This is most noticeable in Plate iv, representing miners' children at school. As a photograph this is a perfect piece of work; but for any indication to the contrary the girls represented might have been pork-butchers' children, and the illustration could, if needed, pass as such. Plate xxi and others, which have little connection with the text, appear to have been introduced merely because they are underground photographs, of which their authors are pardonably proud. BENNETT H. BROUGH.

OUR BOOK SHELF.

The General Principles of Zoology. By Richard Hertwig. Translated by George W. Field. Pp. xii + 226. (New York: Holt, 1896.)

THE English version of the general part of Prof. Richard Hertwig's "Lehrbuch der Zoologie" will be welcome to all teachers of biology in this country.

The value of a text-book of zoology can nearly always be tested by the character of the introductory chapters on the general principles of the subject. To write clearly, accurately and, withal, briefly on such topics as the structure of protoplasm, the character of cells, the fertilisation of the ovum, and the general principles of embryology, requires the knowledge and experience of one who has both investigated and taught for many years.

Prof. Hertwig is a master of his subject, and his "General Principles" is written in a masterly manner.

Among the many excellent chapters in this volume, we may call attention to those on the development of morphology and on comparative histology, which should be carefully read and considered by all those who are engaged in teaching the elementary principles of zoology.

The illustrations are numerous, well chosen, and admirably executed.

Whilst expressing admiration for the book as a whole, it must be noted, with some regret, that Prof. Hertwig writes so confidently of the truth of the hypothesis that the chromatin only is the bearer and transmitter of the hereditary characters. This is a speculation which was never founded on facts, which is not supported by recent investigations, and one which it is to be hoped will soon be lost and forgotten.

The chapter on the geographical distribution of animals is by no means of the same standard of excellence as the others. The statement, on page 216, that the deep-sea fauna is "distinguished from the coast fauna by its archaic character" is not accurate. It is true that a few archaic families have survived in deep-sea water, but by far the greater number of the members of the abysmal fauna are extremely specialised representatives of shallow-water groups.

The translation is good, and we may congratulate Mr. Field on his courage in rejecting the common American translation of the word "anlage" in favour of the more reasonable and intelligible word "rudiment."

British Patent Law, and Patentees' Wrongs and Rights. By Hubert Haes. Pp. xiii + 102. (London: W. B. Whittingham and Co., Ltd., 1896.)

THERE is a feeling among most men engaged in industries that a patent is a bad security for an invention, and that the best way to reap the fruits of an improved chemical process, or of any novel industrial method, is to keep the knowledge secret. This indicates a weakness in the British patent system; and though the matter is a very difficult one to deal with satisfactorily, some change is desirable which will better protect the general public and deal with patentees more justly. Under the system at present in vogue, no examination as to novelty is made before granting the patent. Mr. Haes suggests, among other reforms, that the Government should undertake the most thorough search, in the case of every application for a patent, to ascertain whether the specified invention has previously been patented within this realm. At present this task is left to the patent agents, the Government taking fees but no responsibility. It is stated, "to show in what estimation British patents are held in Great Britain, it is necessary only to mention that, to obtain for an invention a British patent which shall have the likelihood of being valid, it is becoming the custom to apply for the German patent for it. It is found cheaper and quicker to do this than to search the English records, because the German government does that before granting its patent." As the commercial prosperity of our country depends upon inventions, Mr. Haes' statement of patentees' wrongs, and proposed remedies deserves attention.

Diagrams of Terrestrial and Astronomical Objects and Phenomena. By R. A. Gregory, F.R.A.S. (London: Chapman and Hall, Ltd., 1896.)

IN a set of twelve diagrams issued under the above title, the author has supplied a convenience which has been wanted for some time past in the class-teaching of elementary science, thus removing a considerable part of the difficulty experienced in obtaining, in diagram form, results of recent work in any subject. Teachers of physiography will be directly benefited, but most of the diagrams will be found useful in the illustration of geographical and elementary teaching. Many of the figures are almost of necessity similar to previous ones; but even in these cases the treatment is original, the descriptive text being specially clear and devoid of superfluous detail. Evidence of the degree to which recent discoveries are brought up to date is specially well shown in the diagram of "the sun's family of planets," in which the planets Jupiter and Saturn are reproductions from the drawings of these bodies by Profs. Keeler and Barnard respectively, observed by them at the Lick Observatory quite recently. A diagram illustrating the various forms of aqueous circulation is also specially clear and self-explanatory. C. P. B.

The Romance of the Sea. By Fred Whymper. Pp. xii + 468. (London: Society for Promoting Christian Knowledge, 1896.)

"FICTIONS, facts and folk-lore" of the sea make up the pages of this book, but the first and last of these are much more prominent than the facts. Interesting stories, compiled mostly from the writings of others, have been roughly grouped by the author, and the tissue of words here and there makes a slight connection between them. Phenomena of the sea and skies are given some attention, but from the purely descriptive point of view; and the same remark applies to the accounts of sea-monsters, coral, and volcanic islands. Boys with a love of the sea and adventure will be charmed with Mr. Whymper's collected narratives, and they will probably rejoice at the small attempt made to retail scientific facts at the same time.

LETTERS TO THE EDITOR.

The Use of Kites for Meteorological Observations in the Upper Air.

ATTEMPTS to use kites for meteorological observations in the upper air began more than a century ago. The lack of light instruments which record automatically and continuously, prevented the success of the early experimenters. Such records are now obtained for the first time by means of kites at the Blue Hill Meteorological Observatory, near Boston. A history of kite-flying for meteorological observations, with a general account of the work at the Blue Hill Observatory, was given by the Director, Mr. Rotch, in a paper read before the Physical Section of the British Association at the Liverpool meeting (1896). Notes in NATURE of October 22 and 29, vol. liv. pp. 598 and 629, mention briefly the altitudes to which a meteorograph has been lifted at Blue Hill during the past summer. A few of the details of the recent highest ascent may be of interest to the readers of NATURE, especially as it shows that clear and definite meteorological records can be obtained at a great height by means of kites, at a comparatively small expense. The meteorograph weighs three pounds, and records temperature, humidity, and atmospheric pressure. The record of October 8, from the earth's surface to an altitude of 9375 feet above sea level, was as clear and sharp as the records of similar instruments in thermometer screens at the observatory. The temperature-scale on the chart is centigrade, and the humidity pen records 10 per cent. too low, so that 90 per cent. represents saturation. The barograph-pen is made to record altitudes in metre; but it went entirely off the scale, which is too small for the altitude reached. The record was, however, completed on the part of the chart above the scale. A determination of the altitude was made by placing the barograph under an air-pump, and finding the fall of pressure necessary to raise the barograph-pen to the highest point recorded when on the kite. From the amount of fall and the temperature recorded by the thermographs on the kite and at the observatory, the altitude was computed. The altitude was also computed from the angular elevation of the kites and the length of line recorded by a reel, 3 per cent. being allowed for the sag of the steel wire holding the kites. The amount of the sag was determined by previous theodolite measurement, from a long base line, of the altitude of the kites. The altitudes by the two methods agreed within 1 per cent. of the height, and the mean of the two is given. In this ascent nine kites with a total area of about 170 square feet and 18,000 feet of steel wire, weighing about 46 lbs., were used. All the work of the ascent was managed with an ordinary wooden windlass by the three members of the staff—Mr. Fergusson, Mr. Sweetland and myself. The sea-coast is about six miles from Blue Hill, and the general level of the surrounding land is about 100 feet above sea-level. The top of Blue Hill, from which the kites were flown, is 635 feet above sea-level. Cumulus clouds had begun to form when the ascent began, and the meteorograph was soon elevated to the cloud-level, as shown by the humidity record, and was then lowered to remove a defective kite. In the second ascent the clouds were entered at an altitude of 4500 feet. The successive kites added to lift the line as they rose to the cloud-level, and again, when they were drawn below it, gave the data for numerous successive determinations of the altitude of the bases of the cumulus clouds, and furnish an example of the accuracy and frequency with which clouds can be measured in this manner, as shown by the following results:—

	a.m.							p.m.	
Time ...	11.18	1.58	2.05	2.39	3.01	3.34	3.36	4.34	4.57	5.23
Altitude	2974 ft.	4500	4641	5035	5405	5254	5097	5044	5000	5130

These measurements show that the level of the bases of the cumulus clouds rose steadily from 11 a.m. to 3 p.m., then diminished slowly. Theodolite measurements at Blue Hill show this to be the normal daily course of the cumulus. The kite-meteorograph passed above the tops of the cumulus at 3.08 p.m. and the humidity fell in a short time 46 per cent., showing a very dry air above the clouds; a condition which the meteorograph has shown in every case when it was lifted above the clouds, the fall of humidity usually being very rapid after the top of the cloud is passed.

The temperature on October 8 fell below the freezing point at 1.35 p.m. at an altitude of 4540 feet, and continued below freezing until an altitude of 3850 feet was reached at 8.24 p.m. in the descent. At the highest point the recorded temperature was 10° below the freezing point. At the Blue Hill Valley Station at this time the temperature shown by a thermograph was 49° F., making a fall of 29° F. in 9300 feet, or 1° in 320 feet. This fall is slower than the average we have found, which is about 4° in 1000 feet during the day-time, or 1° in 250 feet. During, and immediately preceding, decidedly colder weather the rate of fall increases to about 6° in 1000 feet. The rate of fall is least preceding warmer weather, since a warm wave, as a rule, sets in first aloft.

The ease with which a meteorograph can be lifted to the height of a mile is shown by the fact that this was accomplished three times in four days during August in normal weather conditions. The highest point reached by no means represents the highest point attainable with kites, since at the time of the highest ascent the pull of the kites on the line was 100 lbs., while the breaking strain of the line is over 300 lbs., so that had there been more wire on the reel a much greater altitude might have been reached. Three, or possibly four or five, miles does not seem unattainable in this manner. The importance of such observations for the further developement of meteorology is shown by the fact that the weather conditions at the height of a mile above any station differ more from the weather at that station than does the weather at any place within 500 or 1000 miles at the level of the station on the earth's surface. At the height of a mile in the free air the temperature is usually from 15° to 25° F. colder than at the earth's surface, and there is virtually no daily change in temperature, the nights being as warm as the days. The only changes are due to the passage of warm and cold waves. During fair weather at this height the days are very damp, and the nights extremely dry. Low clouds frequently cover the earth, and even rain may fall from these while the sun shines bright at the height of a mile. The average velocity of the wind at this height is four times greater than at the ground, and hurricanes of 100 miles an hour are not uncommon. At least, the meteorograph records obtained by kites, and measurements of the heights and movements of clouds with theodolites, indicate that these are the conditions which exist above Blue Hill.

H. HELM CLAYTON.

Blue Hill Meteorological Observatory, Milton, Mass., U.S.A., November 20.

The Theory of Dissociation into Ions.

PROF. ARMSTRONG (page 78) says that the chief concern of chemists has been to establish facts; and perhaps this is true; but to an outsider it has seemed recently as if some few facts were unwelcome to the school of chemists represented by himself. For instance, they seemed annoyed at one time with the inertness and the specific-heat-ratio of argon; now he expresses himself as if vexed with the slowness of ionic velocities, and "declines to accept it."

If the ions travelled quicker, a liquid would conduct better than it does, and perhaps that is what Prof. Armstrong desires; but it is difficult to see any ground for his objection to the present state of things. In a rare medium, like a gas, the ions migrate quickly; in a dense medium, like a liquid, they migrate slowly; and their numerical speeds, as measured, exactly for liquids, approximately for air, are not inappropriate to the relative crowdedness. What more can be desired? The facts do not even demand much difference between the gaseous and liquid states; though even if they did they would still have to be accepted, just as the facts of viscosity and its contrary affection by temperature in the two states have been accepted.

I know very well, and have long known, that Prof. Armstrong objects to the idea of perfectly free ions; but surely he is aware that many physicists object to it too, with whatever glimmering of chemical instinct they possess, and they have endeavoured to show that the facts can be expressed without such an hypothesis. Physicists have also objected to the idea of a dissolved salt existing as a free gas in a solvent, notwithstanding the remarkable analogies with gaseous laws, discovered in an admirable manner by physical chemists, that such a substance presents;

and now Prof. Poynting (*Phil. Mag.*, October) shows in detail how the analogies may be accounted for without postulating any dynamical similarity.

There remains the so-called dissociation needed to explain electrolysis. It has been long known, however, that a kind of instability, or ease of interchange, is all that is necessary, not actual permanent dissociation into constituent atoms. What is certain is (1) that the atoms of an electrolyte migrate in opposite directions, and (2) that they require no appreciable electric force to tear them asunder. These are facts, and the instability of composition thus evidenced is such as almost to compel the provisional use of the term "virtual dissociation"; although that condition may very likely be brought about by the loose affinities of outlying members of complex molecular aggregates—a conception which Prof. Armstrong himself promulgated as an hypothesis, but has not yet, I believe, made definite.

The problem presented by the fact of molecular combination is, I suppose, universally recognised by physicists as a difficult but important one, and attempts have been made—by Helmholtz among others—to attack it.

Occasionally it happens that the perennial attempt to reduce one province of chemistry after another, to simple dynamics ultimately, to thermodynamics or electro-dynamics provisionally, meets with some partial success; but it seldom meets with appreciation, perhaps not always with apprehension, from professed chemists. Thus, for instance, Prof. Armstrong seems to speak with some bitterness of "those who are now arrogating to themselves the position of superior persons to whom has been granted the mission and plenary powers to reform an ancient society long steeped in superstition—to wit, the chemists."

Does he intend by such phrases to surround the domain of chemistry with an adiabatic boundary or barbed wire fence for the exclusion of trespassers? I have reason to believe strongly that it is not so, and that it is only his wide knowledge and reading which tends to make him hypercritical.

OLIVER J. LODGE.

As Prof. Armstrong has, in the issue of NATURE dated November 26, continued the discussion on the theory of solution, may I be allowed to point out that there are two entirely distinct questions involved?

The first is to investigate the state of a dissolved substance and the cause of osmotic pressure, and the second to ask what is the physical reason why some solutions possess that property, absent from others, by virtue of which they become electrolytes, have abnormally great osmotic pressure, and high chemical activity.

The answer to the first and more fundamental question remains uncertain. Van 't Hoff's work showed that there was a very close analogy between solution and evaporation, and this led to the idea that there might also be a dynamical similarity between the condition of a gas and that of a substance dissolved in a liquid. Such an hypothesis, although it at once explains the application of the gaseous laws to dilute solutions, neglects the undoubted similarity between the process of solution and certain kinds of chemical action. Prof. Poynting has done a good work in showing that, on certain fairly probable assumptions, the phenomena of dilute solutions can be fully explained by the opposite idea of aggregation. We have, therefore, two hypotheses, each based on an analogy, and each capable of accounting for the facts to be explained. It is probable that neither of them represents the exact mechanical truth, and I imagine that their authors would make no such claim on their behalf. While using both views as guides to future work, we need commit ourselves to neither. Although, personally, I am, at present, inclined to think that some form of chemical theory will ultimately be found to be capable of representing the facts, I have no wish to express my faith in any definite hypothesis. As Prof. Armstrong says, "there is no need to be in so great a hurry—it is no disgrace to admit that we cannot yet explain all the mysteries of the universe."

It will be seen that this first question does not at all involve the second, which refers to the nature of the fundamental property distinguishing an electrolyte from a non-electrolyte. Yet Prof. Armstrong uses Prof. Fitzgerald's warning against prejudging the first question, and Lord Rayleigh's repetition of that warning, as reasons for refusing to accept the evidence for a particular answer to the second.

I may repeat what I said in the letter which appeared in your issue of October 15, that, although there is strong evidence to show that the opposite ions are free from *each other*, there is nothing in the facts of electrolysis inconsistent with the view that they are united with solvent molecules, and that solution is essentially a chemical process, and the cause of osmotic pressure a combination between the solvent and the dissolved matter.

Lord Rayleigh's words, as quoted by Prof. Armstrong, are: "It is to be hoped that chemists will take into grave consideration the emphatic warning that Prof. Fitzgerald has given, particularly as to the danger of supposing that there is any dynamical similarity between the condition of a gas and that of a dissolved substance in a liquid. . . . There is possibly a risk of pushing analogies too far, and of supposing that there is a real dynamical similarity, whereas, perhaps, there is only a similarity in mathematical law."

This statement is clearly meant to apply to the question of the fundamental nature of solution—the question whether or not the dissolved matter is to be considered to exist in a condition dynamically similar to the gaseous state. It does not refer to the second problem, which is concerned with the nature of the property characteristic of an electrolyte. Yet Prof. Armstrong adds: "I, for one, require no better support than this, and shall continue to be, as I have been from the outset, a determined opponent of what, I think, may fairly be termed the nonsensical hypothesis of ionic dissociation."

If the evidence in support of the idea of dissociation is not strong enough to carry conviction to Prof. Armstrong's mind, the supporters of the theory can only mutely regret that they have no chance of making so distinguished a convert; but, when he quotes the words I have copied as an argument against the theory, it seems desirable to call attention to the fact that those remarks were really aimed at something else.

Prof. Armstrong attacks the whole idea of charged ions, and quotes Maxwell to show that it is only a provisional hypothesis. Of course the convection theory of an electrolytic current is merely a convenient way of stating observed facts, such as those grouped together under Faraday's law. It seems clear that the path of the energy used by the current lies in the neighbouring dielectric, just as is the case with a metallic circuit, and it is probable that the real part played by the mobility of the ions is to allow the slipping to go on, by means of which can alone occur that transformation into heat of the energy of the polarised dielectric which we call an electric current. But, whatever the true nature of the process, it is certain that the passage of a definite quantity of electricity through a solution is always associated with the decomposition of a definite quantity of the electrolyte, and, therefore, with the passage in opposite directions of a definite quantity of the opposite products of decomposition—call them ions or what you will. To this extent, then, we are free from hypotheses, and this is ground enough on which to found the whole theory of ionic migration and its consequence, the dissociation of the ions from each other.

Prof. Armstrong complains of the ease with which the dissociation theory can be reconciled with new views as they are developed, and can be made to explain new phenomena as they are discovered. It seems to me that this adaptability goes to show that the fundamental idea of the theory is in accordance with the facts of the case.

I have no desire to defend the moral character of the ions when they have freed themselves from the bonds of that union which Prof. Armstrong seems to think should possess the sanctity of the marriage tie. I fear it is very likely that they *do* form those connections which he has condemned in such very plain language. Indeed, things may be even worse than he suggests. The ions may actually pass from one molecule of the solvent to another, carrying their charges with them, till contact with an electrode ends their career of infamy. Considerable mental agility is needed to follow *all* the metaphors which Prof. Armstrong crowds into a single sentence, but, at any rate, it is plain that this freedom of life clears the ions from the accusations of bearing "water molecules on their backs," and of being "chained to them like galley-slaves."

With regard to the velocities of the ions, I cannot quite see the reason for Prof. Armstrong's belief that they are really higher than is generally supposed. Even on the purely gaseous theory of solution, which Prof. Armstrong here uses to support his argument, the dissolved ions must have very short free paths, and, although the velocity with which they vibrate backwards and forwards from one solvent molecule to another may

be great, when it comes to jostling their way for an appreciable distance in a definite direction through the surrounding crowd of solvent molecules, they will only be able to move very slowly. The migration of the ions is really a process of diffusion under the influence of electric forces, and will, of necessity, be very slow. I can assure Prof. Armstrong that no dissociation apologist will argue "that the charges act as brakes." It is by reason of their charges that the ions are urged forward by the electric forces. Without them, the velocities would not reach even those present figures which appear so despicable, but would merely take the much smaller values given by ordinary liquid diffusion. By placing in contact a coloured and a colourless solution, containing one ion in common, and passing an electric current across the junction, Prof. Armstrong can actually watch the ions migrating, and check the accuracy of the "conventional time-table." W. C. D. WHETHAM.

Trinity College, Cambridge, November 27.

I FEEL sure that many readers, like myself, must have welcomed the sentiments expressed by Prof. Armstrong, in his article on this subject which appeared in your issue of November 26. It seems to me a duty of teachers to protest against the growing tendency there seems to be of putting forward the crude hypotheses of the ionist school, as though they had the same claim to acceptance as well established scientific laws, about which no reasonable doubt exists. So far from this being the case, the arguments commonly advanced in support of this theory seem to consist mainly of the misapplication of physical laws to a few carefully selected cases, aided by plausible but misleading assertions.

The objections that have from time to time been urged against both the views and the methods of argument have never received proper attention at the hands of the advocates of ionic dissociation. (Prof. G. F. Fitzgerald's Helmholtz Lecture; a paper by Prof. S. U. Pickering, *Journ. Phys. Soc.*, vol. xi., &c., remain unanswered.) It is, therefore, with the object of drawing attention to certain further difficulties and, as I conceive, errors in the above theory, rather than of evoking a discussion, that I now write.

In answer to the question—how is it that substances that are supposed to dissociate have "abnormally" large values for osmotic pressure, lowering of freezing-point, and reduction of vapour pressure?—we are told that the dissolved substance exerts the same pressure as if it were a gas and occupied the volume of the solvent, and that when dissociated it exerts a greater pressure on the solvent. Now, surely the term "osmotic pressure" in such a sense is misleading; not only is there no evidence of the substance exerting *pressure* on the solvent, but rather that by an attractive force it can allow water to pass into it, and hold it, up to a certain particular pressure, which, if exceeded, will cause water to pass out again through the semi-permeable wall. There is in this nothing at all comparable to gaseous *pressure*, which certainly never is the cause of another fluid entering it in a closed vessel; for I suppose it will hardly be imagined that in a gas diffusion-cell it is the pressure of the gas inside that causes another gas to pass by endosmosis into it. Similarly with regard to vapour pressure, an attraction between solvent and dissolved substance can account for a reduction of the vapour tension, but a pressure exerted on the solvent by the so-called gasified dissolved body cannot.

In regard to the lowering of freezing-point, we are actually sometimes told that this is a direct effect of the pressure of the salt on the solvent, with a beautiful reference to the lowering of the freezing-point of water by pressure, but with a calm oblivion of the fact that an increase of pressure would raise the freezing-point of other solvents in common use, such as benzene, acetic acid, &c. The alleged fact that the vapour pressures of a solution and of the solid solvent are the same at the temperature of the lowered freezing-point, may be true, but it affords no explanation of the way in which such depression of the freezing-point is brought about.

Ostwald, in his "Outlines of General Chemistry," p. 139, suggests a cyclic change of frozen solvent cooled to $T-\Delta$, melted by addition of the active substance, and raised to T again, but his data are fallacious in not taking into account the considerable difference in specific heat of the solid and liquid solvent, and the consequent variation of latent heat with temperature; so that the heat evolved on freezing and absorbed on melting are not the same as he assumes them to be.

In that same Bible of the ionists a very curious representation of the action of a current on an electrolyte is given (p. 273), where Ostwald states that there is no place for any energy of the current being expended in doing the work of dissociation, and "that it has to perform no work in the matter at all." So much for the researches of Favre, Joule, &c., let alone the most elementary fact that the adverse E.M.F. of polarisation is roughly proportionate to the heat of combination of the electrolyte, and that EQ. units of work must be expended in the transference of Q. units of electricity through the electrolytic cell, quite apart from work done against ohmic resistance. Apparently this idea owes its origin to the observation of Helmholtz, that feeble E.M.F.s can send exceedingly small currents through an electrolyte; but he points out in one of his papers, that if only one cubic centimetre of detonating gas were dissolved in the liquid, "its constituents need only migrate once in thirty-six days from the anode to the kathode in order to produce the observed current." He also showed that under so small a pressure as 10 m.m. an E.M.F. of 1·64 volt is necessary to separate visible gas, while the value calculated from the heat of combination of H_2 and O is 1·49 volt.

In the same chapter (p. 275), Ostwald asks us to "*imagine*" two insulated vessels A and B, connected by a syphon and filled with solution of potassium chloride. Let a negatively charged body be brought near A, remove the syphon and charged body, then A is left with a positive charge. Now, he says, in A there must be an excess of free potassium ions, and if the electricity be conducted away, the potassium assumes its ordinary form, and, acting on the water, develops hydrogen "*which can be collected in a suitable apparatus and tested.*" Now I have calculated the electric capacity of such an arrangement, and supposing a very large beaker and an inductor placed close to it, to be used, the capacity of the condenser so formed could hardly be so large as ·0001 microfarad. We can be generous and suppose that the vessel A is charged to a potential of 50,000 volts above the earth; with this potential the quantity would be 5×10^{-6} coulomb, which would yield approximately ·00000005 milligramme of hydrogen! Did Ostwald repeat the charging by induction, removal of the syphon, and discharging 20 million times, and so obtain a milligramme of hydrogen which he "collected" and "tested." Even if this be "imagined," it would evidently do just as well to leave out the potassium chloride altogether, as water, as pure as Kohlrausch ever obtained it, would, with 50,000 volts, answer the purpose equally well.

When from this experiment (?) he draws the conclusion that—"The assumption that electrolytes contain free ions is not only possible but necessary," one may form some opinion of the kind of evidence that ionists consider conclusive.

In conclusion, I would like to ask ionists the following questions:—

Why do not ions, if free to move under the influence of small external electric forces, attract each other with immense force if they be charged with such enormous quantities of + and − electricity?

Where did they get these charges from?

Does dissociation absorb or evolve heat?

Why does not an E.M.F., however small, liberate gas from dilute sulphuric acid?

Why does solid Ag_2S conduct electrolytically? Is it "dissociated into ions"?

There are many other questions, but I should really like to know the answers to these first. I believe many of the points I have here raised have been brought forward by others before, so I lay claim to no originality in their suggestion, but hope that their consideration may give pause to those who are at present only partly "dissociated," until, at least, some reasonably satisfactory explanations are forthcoming. E. F. HERROUN.

Queen's College, Harley-street, W., December 2.

Responsibility in Science.

MY first letter (NATURE, October 15, p. 572) on this subject maintained that Prof. Poulton had no right to hold physicists as a body *responsible* for views presented by two or three of their number, however eminent. Prof. Poulton (NATURE,

December 3, p. 100) seeks to justify his action on the ground that "in a matter of such great importance . . . it is probably fair to conclude that, with the great majority of physicists, 'silence gave consent.'" This doctrine of silence is surely untenable. If an authority on acoustics pronounces views even on the fundamentals of sound, is an electrician to be held consenting when he forms no opinion or reserves it to himself? In the present case it should be added that whilst questions in geo-physics or astro-physics are often most interesting to the public, they hardly as yet touch the fundamentals of physics, but constitute merely theoretical applications. If we put at 5 per cent. the proportion of physicists who have studied for themselves any given problem in geo-physics, and who have the necessary qualifications to justify the expression of an opinion, we should probably indulge in an over-estimate. It is in fact only a very small minority of whom anything but silence could possibly have been expected.

In the next place, even if the doctrine of silence were accepted, the occasion for applying it does not exist. A considerable number of persons—some in my opinion imperfectly equipped for the task—have criticised the theories of Lord Kelvin and Prof. Tait. In his letter Prof. Poulton represents all such critics as geologists or zoologists, but in his B.A. address (NATURE, September 24, p. 502) he admitted the existence of mathematical critics. Most of these critics had, I think, in reality as much claim to the title physicist as to that of mathematician. I myself five years ago, in two papers whose physical character was indicated by the title "Some Applications of Physics and Mathematics to Geology," while pointing out that in my opinion the critics were mistaken in supposing they had demonstrated the essential erroneousness of Lord Kelvin's work, advocated strongly the maintenance of an agnostic attitude towards the question of the solidity of the earth's interior. These papers appeared in the *Philosophical Magazine*, were reprinted in the "Annual Report of the Smithsonian Institution," and have been referred to since in several standard works. So far as I know, no attempt to controvert their arguments has been published, so that on the doctrine of silence they would seem to represent the views of the "majority of physicists." It is obvious to any mathematical physicist, and I should have hoped to others, that so long as the solidity of the earth's interior is an open question, no theoretical application of the mathematical equations for solids—whether to temperature or any other internal property—can be regarded as final.

My reason for advising Prof. Poulton to allow for possible errors in speculations other than Lord Kelvin's, and for commenting on the absence of any reference on his part to Lord Kelvin's recent experiments on rock conductivity, was as follows:—

The key-stone in Prof. Perry's valuable contribution to the subject, on which Prof. Poulton so largely relies, is the *demonstration* that, even on the assumption of a solid earth, the hypothesis of thermal homogeneousness does not necessarily supply an absolute maximum to the habitable age of the earth, inasmuch as higher estimates can be obtained on the simple hypothesis that the internal strata conduct better than the surface strata. This disposes of the *necessary* character of Lord Kelvin's conclusions on this subject—even if solidity be granted—but still may leave his estimate a not improbable one, so far as physical grounds are concerned, unless a presumption can be raised that the conditions of Prof. Perry's problem exist in nature. A study of Prof. Poulton's address led me to think that in his anxiety to increase the *à priori* probability of the conditions postulated in Prof. Perry's solution, he was attaching undue weight to theoretical speculations which seemed to tell in its favour, while omitting all mention of recent direct experiments by Lord Kelvin which told against it. In my letter I quoted Prof. Poulton's own words, so far as space allowed, and certainly did not represent him as holding the theoretical evidence to be "conclusive."

The second half of my first letter was intended to show Prof. Poulton, by reference to his own address, another aspect of the case, viz. the serious inroads which would be made on a physicist's time if he criticised everything he thought erroneous. It seems that Prof. Poulton agrees mainly with my criticisms, only he maintains that the views criticised are products solely of my imagination. Flattering as it would be to my *amour propre* to believe my imagination so gifted, I must acknowledge the suspicion that most physicists who read Prof. Poulton's address, as published in NATURE, will find a simpler explanation. Take for instance Prof. Poulton's remark, "the earth, even when solid, will alter its form when exposed for a long time to the action of great forces," and my criticism, "here and in the rest of the passage is a strong flavour of the erroneous view that a solid is *rigid* in the mathematical sense, except when viscous under great and prolonged stress." Elasticians, I suspect, will fail to recognise this as the criticism solely of an exuberant imagination.

One word more: Prof. Poulton speaks as if the opinion of "the majority of physicists" were binding on their fellows. Now in the first place the voice of the majority is not yet recognised as dominant in science, and in the second place no provision exists for collecting suffrages. In the society of zoologists and geologists the individual physicist may possibly become a very fountain of universal knowledge, but amongst his peers he is chary about expressing too definite an opinion on questions he has not specially studied. CHARLES CHREE.

December 7.

The Satellite of Procyon.

THE announcement in the Astronomical Column of NATURE for November 19 (p. 62), of the discovery of a close companion to Procyon by Prof. Schaeberle, with the 36-inch telescope of the Lick Observatory, will be extremely interesting to those who know anything of the history of the investigations which have been made as to the cause of the irregularity in the proper motion of Procyon observed by Bessel in 1844, and Madler in 1851. Following up their observations, Dr. Auwers in 1861 computed an orbit on the assumption of a circular motion in a plane perpendicular to the line of sight, round a point about 1″·2 distant, having a period of about 40 years, the position angle being about 90° for 1873, and this, with an assumed motion of about 9° per annum, would make the present angle about 300° for the hypothetical companion.

Otto Struve measured a supposed new companion in 1873, March 28, with the 15-inch refractor at Pulkowa, and found, as a mean of several measures, the P. angle 90°·24, and distance 12″·49; and also in 1874, April 10, when he measured the P. angle 99°·6, and distance 11″·67; but, singular to relate, though looked for with the 26-inch telescope at Washington on several occasions from November 1873 until January 1876, and also by the three Clarks (father and two sons) with the McCormick 26½-inch telescope, Otto Struve's companion was missed by both instruments.

The Washington observers, however, gave estimated places for three new companions within 10″ distance; but when Mr. S. W. Burnham, at the Lick Observatory, examined Procyon on the early morning of November 18, 1888, with a view to confirm all these observations or otherwise, he gave the following record:—"*Procyon*.—Carefully examined with all powers up to 3300 on the 36-inch under favourable conditions. Large star single, and no near companion."

Should the existence of the new companion, now said to be discovered by Prof. Schaeberle, be confirmed by other large instruments elsewhere, the orbit will likely prove to be an excentric one, and that the companion has just emerged from the dazzling rays of the bright primary sufficient to allow it to be measured with the 36-inch; but after the previous experiences in the supposed discovery of other companions, astronomers will be the more inclined to await further observations, especially as the new Yerkes 41⅜-inch object-glass is now ready for mounting at the newly-erected Observatory, and will be in the hands of such keen-eyed and experienced double-star observers as Messrs. Burnham and Barnard.

IN NATURE for March 28, 1889 (p. 510), Mr. J. M. Barr, of St. Catharine's, Ontario, suggested that photography might be employed to obtain the image of a satellite on the sensitive plate by intercepting the image of the brilliant primary by a suitable screen, and in NATURE for April 11 following (p. 558), in addition to other particulars, I referred to the instrumental difficulties connected with getting the impress of a probably faint companion, at the extremely close distance of two to three seconds of arc. ISAAC W. WARD.

Belfast, November 30.

The Leonid Meteor Shower.

IF the recent observations proved that comparatively few meteors of this system were visible, they were interesting as showing the maximum to have occurred on the morning of

the 15th, instead of on the morning of the 14th as expected. In 1879 I found the greatest density of the shower occurred some hours before its probable time, while in 1888 the best display came six hours later than I had been led to expect. Minor returns are, however, more difficult to determine as regards the exact period of maximum, and are likely to teach us little in this respect. The state of the sky, the altitude of the radiant, and the presence or absence of the moon have each an important effect on the visible aspect of a meteor shower, and render fair comparisons from year to year scarcely possible, the circumstances being rarely the same in two cases.

The Leonids in 1896 were certainly more numerous, judging from the majority of the reports, than in an ordinary year, and no doubt a further increase in their strength will be apparent in 1897, but the moon will then rather seriously interfere with observation. Judging from the times of maxima observed in 1799, November 12 a.m., 1833 November 13 a.m.; and 1866 November 14 a.m., the maximum will occur before midnight in 1899; but we have a good prospect of observing the return of 1900 at about 3 a.m. November 15. As regards the next return in 1933, it will probably be well seen from the eastern parts of Europe, while that of 1934 seems likely to be witnessed from England on the morning of November 16. Too much confidence should not, however, be placed in these indications, as the shower has exhibited some irregularities in the past. Thus in 1867 it returned about two hours later than its computed time, while in 1868 it most unexpectedly proved quite a brilliant display about fifteen hours after its time.

W. F. DENNING.

Bristol, December 10.

Oyster Culture in Relation to Disease.

IN Dr. T. E. Thorpe's paper in the issue of NATURE for December 3, there are several erroneous statements which are not calculated to do good. He says that the "Belgian and Dutch oysters chiefly come to Grimsby and Brightlingsea." This is quite wrong, as the greatest quantity of Dutch oysters come to London, some go to Manchester, Liverpool, and other large towns: Belgian oysters are nearly unknown in England.

Again, Dr. Thorpe says that the greatest number of oysters are eaten in September. This again is wrong. The greatest quantity of oysters are sold in the months of November, December, and January.

Again, Dr. Thorpe says "the value steadily increases up to December, and gradually diminishes month by month until it reaches the minimum in June and July." This is not correct, as the better class of oysters do not come to market so late, and the price of good oysters is always maintained.

Dr. Thorpe says, further, "the layings in the bed of the Colne, which presumably furnish the supply for the time-honoured 'Colchester Feast,' are subjected to the comparatively concentrated effluent of Colchester sewage at low water, and to the additional pollution to which the river is subjected at Wyvenhoe and Rowhedge." The oysters sent by the Colne Fishery Board to London and the continent, also those eaten at the "feast," are not fattened in the bed of the Colne, but in a creek lower down the river called the "Pyfleet." On page 28 of Dr. Cartwright Wood's report, reprinted from *The British Medical Journal*, he calls the Pyfleet oyster the standard oyster for purity. Dr. Cartwright Wood, on page 25, also says "these experiments accordingly, as far as they go, tend strongly to confirm the view that in a state of nature the oyster might very rapidly get rid of the effects of contamination."

The Park, Hutton, Essex, December 7. G. H. BAXTER.

BEFORE your correspondent peremptorily asserts that certain statements are "quite wrong," it might be worth his while to ascertain that he was quite right in so doing. To begin with, he has evidently not read the Report to the Local Government Board "On Oyster Culture in Relation to Disease," or he would have discovered that the statements to which he takes exception are made not on my authority, but on that of the Inspector of the Local Oyster Industries. On p. 24 of Dr. Bulstrode's report, under the heading "Oysters imported direct from abroad and consumed without being relaid in our waters," it is stated that "large quantities are also imported from Holland, Belgium, and other countries. . . . I am informed by Mr. Mussun, of Liverpool, with whom I conferred at Cleethorpes, that the chief ports for the introduction of American oysters into this country are Liverpool and Southampton, and for North Sea oysters Grimsby and Brightlingsea."

It is not to be supposed that all the oysters imported into Grimsby are eaten there: no doubt they find their way "to Manchester, Liverpool, and other large towns."

I stated, on the authority of Dr. Bulstrode, that in 1894 27,747,000 oysters, of the value of £84,271, were landed on the English and Welsh coasts by English dredges. Dr. Bulstrode also gives the following table (p. 4), showing how this number was distributed over the several coasts, together with the corresponding value of the oysters.

Month.	Oysters.	Value.
January	2,289,000	£8437
February	2,217,000	7846
March	2,231,000	6838
April	1,768,000	6050
May	2,096,000	5497
June	1,768,000	3948
July	1,694,000	3967
August	2,670,000	6909
September	3,124,000	8054
October	2,947,000	8585
November	2,426,000	7493
December	2,517,000	10,647
	27,747,000	£84,271

This table shows that the greatest number of oysters are landed, and therefore presumably eaten in September, and that their value increases up to December, and then gradually diminishes month after month until it reaches a minimum in June or July.

My remarks on the Colne oyster layings were based on the statements of Dr. Thorne Thorne (p. xii) and Dr. Bulstrode (p. 40). The latter gentleman, after mentioning the fattening grounds in the Pyfleet, which, of course, are distinct from the layings in the Colne, says: "Provided, therefore, that all oysters, prior to consumption, are laid down for a sufficient period on the fattening grounds of the Pyfleet, there is probably no reason to suspect the wholesomeness of Colne Fishery oysters, but it seems to me very undesirable that oysters should be despatched from market direct from the bed of the River Colne."

I have no desire to asperse unduly the character of the Colne oyster, of which, if I were an Essex man, and interested in its culture, I should be as jealous as Mr. Baxter apparently is. I can only hope, therefore, with Dr. Cartwright Wood, that when the Colne oyster finds itself at the sea-side, and "in a state of nature," it not only "might" but will "get rid of the effects of contamination," and rapidly show itself "the standard oyster for purity." Still, on the whole, it is to be preferred that the oyster, like the woman, should be without "a past."

T. E. THORPE.

Radiography.

YOUR columns are eagerly searched every week for information regarding the latest developments of radiography, and for the best methods of working. I think it may be said that we are still in a state of empiricism as to the technique of the subject. We can get fair representations of most of the bones in the human body, though we have much to learn even in this elementary detail. But the definition of the soft parts with sufficient accuracy for diagnostic purposes is still, so far as I am aware, beyond us.

Judging, however, from occasional results, I fancy this desirable point will be reached ere long; for on examining a recent radiograph of a rabbit, I find the masseter muscles well defined, together with accurate outlines of the internal organs. In the case of a partridge, radiographed to discover the cause of "towering," the tendons of the thigh muscles are sharply defined, and in a hedgehog many minute details are perfectly clear. In each of these I gave an exposure of seventy-five minutes, at a distance of 14 inches with a low tension (under 3 inches). I am now using a Rhumkorff coil capable of giving a 10-inch spark, a Watson "penetrator" tube, and Cadett "professional" plates. I should

be glad of information as to the best method of working direct on to sensitised paper, to save the time and expense involved in taking glass negatives. G. M. LOWE.

Lincoln, December 7.

"Chelidonium majus" as a Cure for Cancer.

WITH reference to the probable value of *Chelidonium majus* in the treatment of cancer, I beg to enclose the two following extracts from ancient writers for the purpose of showing that its value, for internal use, was not unknown.

In the "Ortus Sanitatis," of J. A. Cuba, published at Mayence in the year 1491, he makes the following remark, *inter alia*, upon the property of this plant.

"Et ad cancrum oris pulvis radicis cum pulvere rosarum conficitur, et cum aceto decoquitur."

Again, Bodæus à Stapel, of Amsterdam, in his edition of the "Historia Plantarum" of Theophrastus (1644, p. 894), after describing the method of preparing a decoction of the plant, says :—

"Primi liquoris seu elementi aquei usus existimatur, quod *intra corpus* sumptus, omnes humores corruptos et perniciosos corrigit et educat."

Barton and Castle, in their "Flora Medica" (1838), remark that "Linnæus, Murray, Gilibert, and others express their astonishment at the oblivion into which a plant so energetic as the Celandine has fallen, while the ancients knew how to appreciate its qualities." C. LEESON PRINCE.

The Observatory, Crowborough Hill, Sussex, November 26.

Measurements of Crabs.

THE crabs measured by Prof. Weldon, which were 12·5 centimetres long, had the ratio of frontal breadth to carapace length equal to 778·39 thousandths with a quartile deviation of 10·79; the adult crabs had the above-mentioned ratio 604·94 with a quartile deviation of 9·96. He concluded that since 9·96 is less than 10·79 the adults were less variable than the young, and that this diminution of variability might be accounted for by the selective destruction of those young crabs in which the ratio of frontal breadth to carapace length was much greater or less than the average. That Prof. Weldon was mistaken in making this inference may be shown thus :—

If he, in his investigations, instead of considering the ratio of frontal breadth to carapace length had considered its reciprocal, the ratio of carapace length to frontal breadth, he would have arrived at the result that those 12·5 centimetres long had a ratio of carapace length to frontal breadth amounting to 1284·7 thousandths with a quartile deviation of 17·9, while the adults had a ratio of carapace length to frontal breadth of 1653·1 with a quartile deviation of 26. This would have shown that the ratio of carapace length to frontal breadth was more variable (in Prof. Weldon's sense of the word) with adults than with the young. This, he would probably have argued, may be due to the selective *survival* of crabs in which the ratio of carapace length to frontal breadth deviates excessively from the average. But those crabs in which the ratio of carapace length to frontal breadth deviates excessively from the average are precisely the same as those in which the ratio of frontal breadth to carapace length deviates excessively from the average, which latter he concluded were selectively destroyed. Thus the same reasoning applied to the same data leads to two totally irreconcilable explanations. Such reasoning must be false.

Prof. Weldon's erroneous conclusion seems to have arisen from making the mistake he accuses me of making, *i.e.* confusing variability (the quantity measured by quartile deviation) with importance of variability. Having proved that variability in the above sense of the word was less in the case of adult than of young crabs in regard to the ratio of frontal breadth to carapace length, he argues about the diminished variability as if it were the same as diminished importance of variability, which is in the general case measured by ratio of deviation to average amount of the quantity measured. J. A. COBB.

Minneapolis, November 25.

Diselectrification by Phosphorus.

IN No. 1410, vol. lv. of NATURE, Mr. Shelford Bidwell refers to the discharge of electricity by phosphorus when it is oxidised. In a paper published by Prof. Naccari (*Atti della Science di Torino*, vol. xxv., February 22, 1890) as well as in one of our own (*Wiedemann's Annalen*, xxxix. p. 321, 1890), you will find a record of this observation. ELSTER AND GEITEL.

MANY thanks for sending me the above. I much regret that I did not know of the experiments referred to. I made a considerable search before sending you my letter; but it is so difficult to ascertain what has been done before, that one hesitates to publish anything. SHELFORD BIDWELL.

Riverstone Lodge, Southfields, S.W., December 2.

Cultivation of Woad.

LATELY at Leighton Buzzard, I saw an old book, "E. Bowen's Complete System of Geography, 1743," in which some account is given of the growth and preparation of woad in Bedfordshire. There is a Woad Farm at Lathbury Bridge, near the confluence of the river Lovat, or Ouzel, with the Ouse, at Newport Pagnell, Bucks, and commented upon in the *Bucks Standard*, November 8. The author [name not given], after referring to the more ancient growth of woad, gives it as his opinion that, "this once largely used herb was grown on this farm at a later period, and hence its name."

The lands of the Woad Farm are alluvial clay and river gravel, and there is an osier-bed in the locality.

December, 1896. A. C. G. CAMERON.

Dormant Seeds.

THE remarkable experiments of Prof. C. de Candolle reported on p. 21, and those formerly described of Prof. Giglioli, seem certainly to show that life in a seed may be prolonged indefinitely under suitable conditions; or rather, that so long as no destructive change occurs, the power of living, not necessarily life itself, persists in the protoplasm. It has occurred to me as *barely possible* that some seeds from amber might be made to grow. It sounds a very wild suggestion, but the conditions of perfect preservation, with protection from air and moisture, are peculiar, and should offer as good a chance as some of those arranged by Prof. Giglioli, or cited by Prof. de Candolle.

T. D. A. COCKERELL.

Mesilla, New Mexico, U.S.A., November 19.

The Arrangement of Branches of Trees.

MAY not the want of symmetry or the "anyhowness" of the arrangement of the branches of trees serve some highly useful purpose? May it not help to prevent the trees being overturned in the highest winds by the want of synchronism in the motions of the branches? I have never seen or heard of such an idea, and it may be open to serious objections; but some time ago I watched the branches of a large plane tree, still partially in leaf, during a high gale, and it seemed incredible the tree could stand, but for the fact that whilst one large limb was swaying one way, another would be swaying the opposite way, and so on, all plunging and bending anyhow, with no two in harmony. Some of the larger limbs would swoop down as others bounded up in a sudden gust, and some swaying laterally with the wind would be balanced by others at another part of the tree swaying against the wind.

The oak, the beech, the ash, and so on, have all this "anyhowness" of branch arrangement, they at the same time being our largest trees and most in want of it.

Do the early stages of tree evolution point to a more methodical mode of branching? THOS. SWAN.

Maryfield House, Leslie, Fife, December 11.

Curious Purple Patches.

REFERRING to "Purple Patches," in NATURE of November 12, I have frequently seen patches like those mentioned, but not quite so large, on the decks of ships immediately after they had been scrubbed with *salt water*. I have also seen them in bad weather at sea when salt water was coming over the side. I never remember noticing them after rain, or at any other time than when salt water has been on the decks.

The idea I have always had, and heard others at sea speak of, is that they were small salt-water organisms squashed out by the foot.

I have noticed them most frequently on the Scottish coast, but I have also seen them in China. Out here I have not observed them. E.

Mediterranean Station.

FASCINE TRAINING AND PROTECTION WORKS.

IN the *Engineering Magazine* (New York) for June is an interesting illustrated article on "Bank Revetment on the Mississippi," with illustrations showing the condition of the banks of the river after "caving" and the method of making and fixing the fascine mattress work used for their protection.

The lower part of the Mississippi runs through a vast alluvial plain, the surface of which is below the level of the water in the river in times of flood. This land is protected by banks locally known as "dykes" or "levées," which prevent the flood water from inundating the district. The first of these banks was built at New Orleans in the early part of last century. They are constructed of the earth taken from surface of the ground close by, and are constantly liable to damage by floods. Some of them are of considerable dimensions, and of sufficient width at the top to form a roadway for carts and other vehicles. From time to time these banks have been extended until there has been developed the great levée system which extends nearly from Cairo to the Gulf of Mexico, protecting an area of about 30,000 square miles of rich land and numerous towns and villages, and guiding the floods in a permanent high-water channel to the sea.

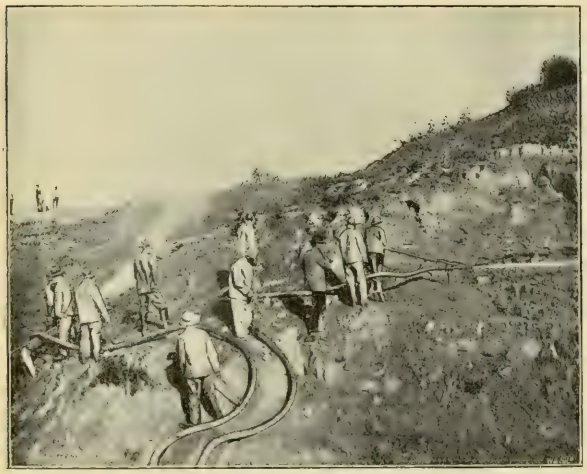

FIG. 1.—Details of Hydraulic Grading.

These banks are a constant source of care and anxiety to those who have charge of them, being subject to "caving" caused by abrasion; the action of soakage water; and the undermining of the foot of the slope by the current. To prevent this caving, and for the repair of the bank, where it has taken place, brush and stone revetments are used. The material for this purpose is principally live willow or cotton wood poles from 25 to 30 feet long, and fascines fastened together in the form of mattresses by iron wire. No revetment work in the world approaches the magnitude of that undertaken on the Mississippi. Here mattresses, having a superficial area of seven or eight acres, are sunk in the bottom of the river in depths of from 80 to 100 feet, and in currents flowing at the rate of from 4 to 5 miles an hour. Dykes 430 feet long by 60 feet high, containing 80,000 feet of lumber, 2000 tons of rock, and nearly 20,000 lbs. of iron wire and rods, are placed in the water in a depth of 150 feet.

The mattresses are constructed by first building on floating ways a rigid head of poles, to which weaving poles are fastened at right angles. On these, woven willow brush is laid; a grillage of poles is then fastened to the top, and after being secured to the bank and mooring-barge, the mat, 400 feet long by 150 feet wide, is sunk by means of large stones thrown from the barges. After sinking the mat the upper portion of the bank is levelled to a regular slope by what is termed an "hydraulic grader." This machine consists of a pump having a discharging capacity of 2000 gallons a minute, fixed on a barge. The hose from this pump terminates in a 1¼-inch nozzle, from which the water is directed on the bank at a pressure of 160 lbs. on the inch, reducing it to the required slope. By this method the excavation of one cubic yard of earth takes a fraction less than one cubic yard of water, and uses 3 lbs. of coal. The height of the bank thus graded often averages 30 feet, and the material removed along a length of 100 feet, about 3500 cubic yards, costing about 4 cents (*2d.*) per yard for removal. When the bank is levelled and dressed to the required slope, a revetment of two layers of brush, with pole grillage above and below, fastened with wire and spikes, is placed thereon and then covered with stone. Another method of protection is by fascine mats made of bundles of poles 3 feet in diameter, laid normal to the bank; to these is fastened at intervals of 8 feet a 5/16-inch wire cable and ¼-inch wire strand. Fascines 11 inches in diameter, made of bundles of willows, are then placed parallel to and against the head, and held in place by a turn of the wire, and the operation repeated until the desired size is attained. These woven mats often have dimensions of 300 by 1000 feet. To build and sink a fascine mattress 300 feet wide, requires from 250 to 300 men, and the average progress per day is about 150 lineal feet. Of the finished cost about 45 per cent. represents labour, and 55 per cent. material.

The article in the *Engineering Magazine* only deals with fascine work as applied to the maintenance and repairs of the banks of the river. The jetties at the mouth of the Mississippi, constructed for the deepening of one of the outfalls of the river into the Gulf of Mexico, for the purposes of navigation, were constructed entirely of fascine mattresses. In order to improve the depth from the gulf into this magnificent river, which has a navigable water-way extending over 16,000 miles, Captain Ends advised the training of one of the principal outlets, and so by confining the water within defined limits, and increasing its velocity and scouring power, to obtain greater depth. He undertook to carry out the necessary works to effect this purpose without receiving payment unless he succeeded in obtaining a channel 200 feet wide with an average depth of 26 feet, and a central depth of 30 feet. This he successfully accomplished. The east jetty is rather over two miles in length, the other being a little shorter; the effective width between them is 700 feet. The mattresses used in the construction of the jetties were made principally of willows brought from the swamps over distances varying from 20 to 300 miles;

these were weighted with stone brought down the Ohio River from a distance of 1320 miles, the quantity used amounting to 100,000 cubic yards. The mattresses used were about 100 feet long, and from 40 to 50 feet wide. They were built on inclined ways at the head of the Pass, and when completed launched like a boat and towed floating to their place along the line of the jetty, and then loaded with stone and sunk. The same method of training the outfall of the river has been adopted on other parts of the coasts of the Gulf of Mexico and of the United States.

The jetties at the mouth of the river Maas, in Holland, were also constructed of fascine mattresses in a somewhat similar way. These piers are about one and a half miles in length, and terminate in a depth of twenty-two feet at low water. Experience shows that their elasticity saves them from any damage from the shocks caused by the impact of the waves. They were economical in construction, and have been found after twenty years' experience to stand the wear and tear of the waves of the North Sea. The great dam across the Zuyder Zee at Schellingwoude, in connection with the North Sea Canal, was also constructed with fascine mattresses on the exterior, the centre part being filled in with earth.

Owing to the scarcity of material for making the fascines, this system of mattresses has not been employed in this country. But more than half a century ago fascine training walls were largely adopted for the improvement of the four large Fen rivers emptying into the Wash, and this system is still in use. They have answered their purpose admirably. The fascines are made of thorn faggots about three feet in girth, tied together by tarred rope. These faggots are brought to the spot where the training wall is being constructed in barges, and placed in layers, the number of faggots in width depending on the height the wall is to be carried. Each layer is covered with clay or marsh sods, and the side next the river finished to a slope of about six inches horizontal to one foot vertical, the brush ends being placed outwards and trimmed up. Sometimes the faggots are staked down, but this, as a rule, is not found to be necessary. This method of training has by experience been found to be economical, durable, and efficient; and has this great advantage over stone training walls, that vessels which by accident run on to the walls are not damaged in the way they are when they come in contact with the stone.

A full description of this work, and also of the mattresses used in Holland and America, with illustrations, will be found in the chapter on "Training," in the work on "Tidal Rivers," added a short time ago to Longmans' Engineering Series.

Fig. 2.—Constructing Fascine Mat on Mattress Ways.

SIR WILLIAM MACGREGOR'S RECENT JOURNEY ACROSS NEW GUINEA, AND RE-ASCENT OF MOUNT VICTORIA.[1]

BY the courtesy of the Prime Minister of Queensland, Sir Hugh M. Nelson, I have been favoured with the following copy of a telegram from His Excellency the Administrator of British New Guinea to His Excellency the Governor of Queensland :—

"Without loss of life or limb have crossed New Guinea from mouth of Mambare to mouth of Vanapa. Followed Mambare to foot of Mount Scratchley where river divides to embrace the mountain. Ascended Mount Scratchley, on top of which observed with small theodolite. Found easy road west of Stanley Range, without descending re-ascended Mount Victoria to observe, but weather unfavourable. Descended Mount Knutsford, and found a not difficult road to coast. The miners have been at work at foot of Scratchley, probably the whole of which is auriferous. Wharton Chain connects Mount Scratchley with the great Mount Albert Edward, which is also well inside British territory. All these great mountains seem composed of slate and quartz. No natives between Government Station and Mount Scratchley. On the latter is very friendly tribe. Excellent relations with natives from Mount Knutsford to the coast. Had scarcely a single completely dry day. I strongly dissuade any travelling towards the interior before April or May. Native carriers will not be permitted to proceed inland with Government sanction before then, when all possible facilities will be given to prospectors during the dry season. (Signed) "Wm. MacGregor."

It is well known that in 1889 Sir Wm. MacGregor, who at that time had but very limited resources at his command, successfully accomplished the ascent of the Owen Stanley Range to its highest summit, which he named Mount Victoria.

In the course of my official duties, the work of compiling the map illustrating the explorer's route on that occasion devolved upon myself, and I am consequently morally responsible for the correct delineation of all the features upon it, although this does not appear on the face of the map itself. At the same time I had the privilege of being the first to deal with, examine, and make public the geographical results of that famous journey, in a paper read, in Sir Wm. MacGregor's presence, at a meeting of the Royal Geographical Society of Australasia, Brisbane, on September 2, 1889. I mention this to show that I have an intimate knowledge of every detail connected with the work and results

[1] Read at a special meeting of the Royal Geographical Society of Australasia, Brisbane, October 30, 1896.

of the expedition in question, and am fully prepared to enter into all the particulars of it, even more fully than I have done on a previous occasion, or in my work on "British New Guinea."

For many years before the arrival of Sir Wm. MacGregor in New Guinea, several attempts had been made to explore the Alpine region of the Owen Stanley Range. For various reasons, no one had been able to accomplish it. These attempts, by Captain Armit, Messrs. Chalmers, Goldie, Morrison, Hartman, Hunter, Cuthbertson and Forbes, resulted in signal failure, neither of the explorers reaching even the foot of the great range. In a letter published in the *Proceedings* of the Royal Geographical Society, London, September 1890, Mr. H. O. Forbes stated that his "nearest approach to Mount Victoria, by my own map, is between eight and nine miles," and that it was only necessary for him to descend to and cross the Warume River below him to obtain access to several leading spurs running directly to the summit of Mount Victoria. He believed that the road traced by his eye from the hills in the Sogeri region on his first arrival in New Guinea was more eminently feasible than the one followed by Sir Wm. MacGregor in the latter's journey to the summit of Mount Victoria. Against this statement it may be pointed out that there seems no doubt whatever that Mr. Forbes did not see the highest crest of the mountain from his nearest approach to it, and it is almost certain that he could not have obtained access to the crown of Mount Victoria along the south-easterly spur of it. Concerning this accessible spur which Mr. Forbes purposed ascending, Sir Wm. MacGregor says, it is a mighty precipitous buttress exceeding 12,000 feet in height "bristling with peaks and pinnacle-like rocks, and contains hundreds of inaccessible crags and precipices."

Sir Wm. MacGregor's route lay for some distance up and along the Vanapa River, and apparently he has followed his old track very closely from the crown of the Owen Stanley Range to the South Coast in his recent journey across New Guinea. The important bearing which the successful accomplishment of this remarkable journey must necessarily have upon the development of the country will be fully apparent to all who have watched the progress of British enterprise in the possession since its establishment some ten years ago. Apart from the increase to our knowledge of the geographical conditions of the interior of the south-eastern portion of the island itself—an increase that cannot fail to be of the very greatest interest and importance—the advantage of having a practicable trade route across the British Territory is one that can scarcely be overestimated. It is almost impossible to give an accurate forecast of its bearing upon the opening up and settlement of the country and the development of its mineral resources. That valuable minerals occur in the high ranges of the interior has been clearly enough shown by the alluvial gold obtained in the upper reaches of the Mambare River, and the auriferous character of Mount Scratchley, to which special mention is made in Sir Wm. MacGregor's telegraphic message to the Governor of Queensland. There is little doubt, too, that mineral deposits will also be found on the southern slopes, or near the base of the Owen Stanley Range, and this region will soon be rendered accessible along the overland trade route passing the western spurs of the range in question.

The Mambare River (the Clyde of the Admiralty Charts) debouches into Traitors Bay on the north-east coast of the possession. The mouth of this interesting river is only about two miles inside the Anglo-German boundary, on the 8th parallel. It is navigable for an ordinary-sized steam launch for about forty miles up, and on the lower reaches are extensive areas of good alluvial land interspersed with remarkably fine fields of sago palms. The district is famous for its very lofty forest trees and fine climate. The river was explored for the first time by Sir Wm. MacGregor in 1894, and recently he again ascended it on his journey across the island. There is no doubt but that it affords easy access to the mineral areas of the interior, and especially to the bracing highland zones of the Owen Stanley Range, Mount Albert Edward, Mount Scratchley, and other neighbouring ranges, that were hitherto regarded as inaccessible. It forms an easy section of the great overland trade route now discovered, and for the first time opened up by the Lieutenant Governor, and it is almost certain that the Mambare district will ere long become one of the most important in British New Guinea.

Excellent relations have been established with the natives of the interior, and indeed all along the overland route the natives met with have been very friendly, a prevailing condition that will have an important bearing upon the future development of the country by British enterprise.

Not the least important geographical results of Sir Wm. MacGregor's recent journey is the discovery of a connecting chain between Mount Albert Edward and Mount Scratchley, and the practicability of ascending the Owen Stanley Range to its highest summit on Mount Victoria from the north-east as well as from the opposite side.

J. P. THOMSON.

JOHAN AUGUST HUGO GYLDÉN.

THE ranks of astronomers have suffered severely of late, and it is with deep regret that we are compelled to record that the Royal Observatory of Stockholm has now lost its renowned Director. Prof. Hugo Gyldén could ill be spared, especially at such an early age as fifty-five. On November 9 last he was seized with paralysis of the heart, and died during the afternoon at the Observatory. The following particulars of his life and work have been gathered from the obituary notices contributed to the *Astronomische Nachrichten* by Herr Karl Bohlin, and to the *Comptes rendus* by M. Callandreau.

Hugo Gyldén was born at Helsingfors in the year 1841 (on May 29), his father, Nils Abraham Gyldén, being a professor of Greek at the University. At the age of sixteen he went to the University of that town; after first studying chemistry, and, at a later date, mathematical astronomy, he gained in 1860 the title of "Magister der Philosophie." To make his studies more complete he went abroad, and during the years 1861–62 he was found at Gotha and Leipzig, having come in contact with Hansen, Le Verrier, and Delaunay. In December of 1862 he was elected a Teacher of Astronomy, and in the following year a Doctor of Philosophy.

Pulkowa saw him first in 1862, and after a year's work there he was made an "Adjunct Astronom," being promoted in 1865 to "Älteren Astronomen." The following year he received the title of "Hofrath."

About this time his investigations related to the constitution of the atmosphere and refraction, which form now the basis of the refraction-tables at Pulkowa. At the same time, also, he was busy with elliptic functions in their relation to the "mécanique céleste," the first results of which appeared in the *Studien auf dem Gebiete der Störungstheorie*, I., 1871.

The important service he thus rendered to astronomical science led the Royal Academy of Sciences of Stockholm to offer him the vacant place of Astronomer of the Academy and Director of the Observatory in Stockholm. This he accepted and retained until his death.

His activity, while holding this office, was displayed not only in the development of pure scientific works, but in drawing around him a number of students, among which may be mentioned O. Backlund, A. Donner, P. Harzer,

A. Shdanow, E. v. Haerdtl, M. Wolf, M. Brendel, V. Wellman, and H. Masal.

Such was his renown on the continent, that pupils came from all countries to study under him and hear his lectures. He was one of the few who knew how to communicate to his hearers the noble passion for the science which animated him. His enthusiasm raised the expectations of his pupils, while, at the same time, their spirits were benefited by the rich ideas of their master. Gyldén was a true teacher whose noble character obtained respect, while his simple and cordial nature inspired affection.

Astronomers know that to Gyldén a great advancement of the astronomy of precision is due; his admirable series of observations with the meridian circle hold a high place of honour.

He wrote his celebrated historical representation of astronomy, which appeared later (1877) in the German language as "Die Grundlehren der Astronomie." He was also the founder and publisher of the observatory publication "Iakttagelser och undersökningar anställda på Stockholms observatorium," which contained not only the results of the observations with the meridian circle, but theoretical investigations carried out by him and, to some extent, by his pupils.

Gyldén, is above all, known in the world of science by his works that he pursued since the death of Le Verrier, on the general theory of perturbations. In proceeding to a revision of the methods of approximation in the "mécanique celeste," he has rendered the most eminent service to this branch of science.

Having completed the main points of his investigations on the intermediate and absolute orbits of the heavenly bodies in a series of publications, "Undersökningar af theorien för himlakropparnas rörelser," I.–III., 1881–1882, he was able in 1884, by means of a grant of money from his Government, to make considerable progress in the application of his theory to the solar system. It was his intention to bring together all the results in one work entitled "Traité analytique des orbites absolues des huit planètes principales," but only the first part, containing the analytical developments of the absolute orbits, has as yet appeared. Gyldén, unlike Tisserand, did not have the satisfaction of leaving behind him a complete work.

Unfortunately he was denied the labour of completing the necessary numerical calculations. On the other hand it was a great pleasure for him to see his last great work, consisting of tables giving the coefficients, in the expressions of the perturbations, dependent on the proportion of the half-major axes, in a nearly completely printed condition. This was brought about by the generous assistance of Miss Bruce, who supplied the necessary means.

In the year 1884 he was called by the University of Göttingen to fill the post of Professor of Astronomy there; but, following the expressed wish of the Stockholm Academy of Sciences, he remained, receiving, through the generosity of the King, means to deliver lectures at the University. Since 1888 he was an active teacher of astronomy at the High School in Stockholm.

The results of Gyldén's many and varied scientific studies on stellar parallaxes, proper motion of stars, explanation of certain variable stars, application of partial anomalies, conveyance of perturbation developments, cosmical questions, &c., have appeared in a series of large and small treatises, in the *Acta der Akademie der Wissenschaften*, and the *Acta Mathematica*.

Besides being a member of several foreign Societies, he was President of the Astronomischen Gesellschaft from 1889 to 1896.

Gyldén has left behind him a widow, two sons and two daughters, besides numerous friends, scattered in different parts of the world, who lament deeply the loss of a kind friend and sympathetic fellow-worker.

NOTES.

THE final entombment of M. Pasteur is to take place on the 26th of this month, at the Pasteur Institute. The reason why so inconvenient a day for English people has been fixed is that the 27th is the anniversary of Pasteur's birth, and as that day falls on a Sunday this year, the Saturday previous was chosen as more suitable. The ceremony is to be semi-official and *semi intime*. The members of the family and a few intimate friends will attend a short religious service at Notre Dame, where Pasteur's remains have in the meantime been deposited, and members of the Institute of the Academy, the representatives of the Government, and delegates from learned societies and foreign countries will meet the cortège on its arrival at the Pasteur Institute at 9.45 a.m. It is expected that Sir Joseph Lister will represent the Royal Society, Sir John Evans the British Association, Sir William Priestley the University of Edinburgh, and Sir Dyce Duckworth the Royal College of Physicians. The mausoleum in which the remains of the great investigator will find their last resting-place, is a fitting memorial which has taken more than a year to complete, and will be decorated with various designs indicative of Pasteur's work and of the benefits he has conferred on humanity and the several industries.

DR. BEHRING, the discoverer of the anti-diphtheritic serum, has had the Grand Cordon of the Crown of Italy conferred upon him.

THE German Emperor has conferred upon Dr. Roux, of the Pasteur Institute in Paris, the Royal Order of the Prussian Crown of the second class.

LADY PRESTWICH has given to the Geological Department of the British Museum the collection of fossils formed by her husband, the late Sir Joseph Prestwich.

IT is reported that Dr. Thorne-Thorne, chief medical officer of the Local Government Board, has arrived at Brussels, accompanied by a colleague, to study the vaccination system in Belgium and the laws and regulations bearing upon the subject.

THE death is announced of M. Alfred Nobel, whose name is well known in connection with the invention of dynamite and similar high explosives.

Globus (vol. lxix. No. 24) announces that the waters of Lake Titicaca continue to subside with astonishing rapidity. A large area of land has been exposed on the northern shore.

LIEUT. HOURST, whose explorations in the Niger region were referred to last week (p. 133), arrived in Paris on Sunday last. The *Times* correspondent says he was welcomed at the railway station by representatives of the Colonial Office, the French Africa Committee, the Egypt Committee, the Paris Geographical Society, and the Explorers' Society. He has made a splendid collection of sketches and photographs.

MR. J. E. S. MOORE, of the Royal College of Science, London, who has been investigating the African Lake Fauna, has this week notified his safe return to Zanzibar. In a letter, dated August 10, he reported himself about to start on his last dredging trip. He has made extensive zoological and geological collections; and in the correspondence which he has sent home, he announces, among other things, the discovery of an apparent dimorphism in the Tanganyika medusa, with active budding in both forms.

IT is reported that the bubonic plague shows no abatement at Bombay. So far, eight hundred deaths have been reported; but the actual number is believed to be much larger. The *British Medical Journal* has drawn attention to the serum prepared by Dr. Yersin at the Pasteur Institute in Saigon for the

treatment of the plague; and the authorities in Bombay are urged to request Dr. Yersin to visit their city, and to afford him opportunities of practising his serum injections on the plague-stricken. The success claimed for the serum in Amoy, China, can be readily tested in Bombay.

REUTER reports that at Laurvik, on the southern coast of Norway, near the Swedish frontier, about nine o'clock on Monday morning, a wave of earthquake was perceived, taking the direction east to west. Several houses shook. At Karlstad in the province of Wermland, in Sweden, at 8.30 a.m. on Sunday, December 13, there occurred two very strong shocks of earthquake following each other in quick succession from south-east to north-west, and lasting about twenty seconds. Houses trembled, and furniture was thrown down. Seismic disturbances were also felt at other places in the province of Wermland. The shocks in this district were preceded by loud rumblings.

WE are gratified to know that the year 1896 has not been permitted to pass without the formation of a strong and representative Committee to promote a national memorial to Dr. Edward Jenner. At a meeting held at St. George's Hospital last week, Sir Joseph Lister occupying the chair, it was resolved, upon the proposition of the Bishop of Rochester: "That the present year being the centenary of the first successful vaccination is an appropriate time to inaugurate a work of national utility in honour of Edward Jenner." The resolution was seconded by Lord Reay, and supported by Sir Richard Quain and Dr. Michael Foster. Lord Glenesk moved the second resolution: "That a subscription be set on foot with the view of founding some institution of a nature to be hereafter determined in connection with the British Institute of Preventive Medicine to be distinguished by Jenner's name." Dr. Wilks, in supporting the resolution, said that every civilised country in the world had accepted this discovery. We alone had no great national monument. Prof. Burdon Sanderson, Mr. Jonathan Hutchinson, Dr. Bond and Dr. Glover also expressed their support, and the resolution was passed. Prof. Clifford Allbutt moved: "That a public meeting be called early in 1897 to consider the resolutions passed at this meeting, and to finally decide the form of the memorial." He urged that the memorial should involve means of carrying on research. The motion was seconded by Mr. Brudenell Carter, and agreed to. A Committee, containing not only the names of a number of distinguished men of science, but of other men of "light and leading," was nominated by the meeting; so we may confidently expect to see, at no very distant date, a worthy monument erected in recognition of Jenner's work and merit.

THE steamer *Wilkommen*, which arrived at New York from Dantzic a few days ago, is reported to have had a novel experience. On the morning of November 17, in lat. 48° 10′ N., long. 44° E., an immense meteor fell from south-east to north-west, and leaving a trail of light which remained visible for several minutes, entered the ocean apparently about two miles ahead of the steamer. Fifty minutes later a great wave swept over the steamer, but there is no evidence that this had any connection with the fall of the meteor.

THE preparation of a flora of Russia is being arranged, according to a *Daily News* correspondent, by the Imperial Natural History Society of St. Petersburg. An appeal is to be sent to all institutions and persons occupied with the study of botany to assist in the work. The flora of European Russia will be published first, and followed in time by those of Asiatic Russia and the Caucasus, the material being acquired from voluntary workers. It is hoped that the undertaking will meet with support and encouragement because of its great scientific importance.

PROF. G. VICENTINI and Prof. G. Pacher, writing in the *Atti e Memorie* of the Academy of Padua, describe several interesting results obtained with the current of a Tesla transformer, the most noteworthy effect being the production of shrill musical sounds with a disposition of the apparatus which the authors propose to call an "electrical syren." The phenomenon in question presents several peculiar features.

AN apparent proof of the inheritance of acquired characteristics was obtained two years ago by Mr. Leonard Hill, in experiments upon guinea-pigs, the results being briefly described by him in these columns (vol. 50, p. 617). From a note in the current number of the *British Medical Journal*, upon a recent discussion at the Zoological Society, it appears that further experiments has led Mr. Hill to a conclusion opposed to that provisionally expressed in his letter to us. According to our contemporary, Mr. Hill has been entirely unable to confirm the experiments by which Brown-Séquard determined the inheritance of acquired characteristics. By division of the cervical sympathetic nerve, a permanent droop of the upper eyelid can be obtained. This Brown-Séquard stated to be inherited by the young. Mr. Hill divided the nerve in six guinea-pigs on the left side, but none of the children inherited the permanent droop of the eyelid. He again divided the nerve in twelve of the children, and interbred them, but none of the young inherited the permanent droop. A temporary droop of either the right or left upper eyelid, frequently observed in the young, was caused by conjunctivitis arising from infection of the eye at birth, for the young were never born with the droop. With the conjunctivitis disappeared the droop, which was not due to paralysis, but to photophobia, and often disappeared on sudden excitation of the animals.

THE actual state of affairs as to the attempt to prevent free access to the Giant's Causeway was described at a recent meeting of the Belfast Naturalists' Field Club, by the President, Mr. Lavens W. Ewart, in the following words:—"A few speculators have banded themselves together to endeavour to exclude the public from free access to this truly gigantic creation, and they have invoked the Court of Chancery to establish them in this undertaking. Three gentlemen, of whom, unfortunately, I am one, have been served with writs in respect of so-called trespass, and the battle has begun. A committee had already been formed to protect the rights of the public, and they are defending the action. Owing to the fact that the Causeway Syndicate is a public company, they cannot be required to give security for costs, and as their capital consists of, I am informed, but 7*l.*, whether we win or lose, we—that is to say, the Causeway Defence Committee—will have to pay our own costs. Our solicitors estimate that the costs may amount to 400*l.*, and this sum at least we must raise. We ask for help in the matter of collecting subscriptions, and collecting lists will be supplied to all who will take them. Large subscriptions, as a rule, are not asked for, but small sums given by the many, for it is a matter which concerns the many. Evidence is also wanted from those who have known of the Causeway as a public resort for forty or fifty years or more."

THE Anthropological Institute of Great Britain and Ireland has successfully promoted the study of the science of man ever since it was founded; and the twenty-five volumes of the *Journal*, now complete, contain abundant evidence of the extent to which the Institute has contributed to the progress of anthropology in the last quarter of a century. The Council are anxious, however, to obtain a greater measure of public support, to see a larger attendance of Fellows and their friends at the meetings, to increase the number of papers printed in the *Journal*, and to illustrate them more fully, and to aid in many

other ways in the progress of anthropological research. "In most continental countries," rightly remarks the President, Mr. E. W. Brabrook, "the means of doing this would be found in a subsidy from the State, and few appropriations of public money would be more worthy or more likely to prove reproductive, in benefit to the community at large, than a payment in aid of anthropological work. In this country, however, it is the practice to leave work of this kind to those who show a voluntary interest in it by joining the Institute as Fellows." It is hoped, therefore, that the number of Fellows will be largely increased, so as to increase the usefulness of the Institute, and assist still more actively the progress of anthropological science.

WE have been glancing through a new list of the staffs of the Royal Gardens, Kew, and of botanical departments and establishments at home, and in India and the Colonies, in correspondence with Kew. If evidence of the influence of Kew upon the advancement of botanical science is ever needed it will be found in this list, published as Appendix III. to the *Bulletin of Miscellaneous Information*. Nearly seventy members of the staffs of botanic gardens in diverse regions of the world are marked as having been trained at Kew. No establishment that we know of can present a better record of work accomplished, and none could desire a worthier testimonial of efficiency than that shown by the wide distribution of Kew men. For the information of directors, superintendents, and curators in botanic gardens across the seas, we announce that a list has just been published of seeds of hardy herbaceous annual and perennial plants and of hardy trees and shrubs which, for the most part, have ripened at Kew during the year 1896. These seeds are not sold to the general public, but are available for exchange with colonial, Indian, and foreign botanic gardens, as well as with regular correspondents of Kew. No application, except from remote colonial possessions, can be entertained after the end of March. The list is published in the *Bulletin* for 1897, Appendix I., an advance copy of which has been sent us.

DURING the last fifty years much work has been done by marine naturalists all round the British coasts, with a view to determining the distribution of those animals which live on the floor of the sea. It has been fully recognised that the localities frequented by many marine species are very definite and extremely limited in extent, and that both the nature of the sea-bottom and the creatures which live there exhibit as much variety as we are accustomed to find on land. The Marine Biological Association, with the assistance of a grant made for the purpose by the Royal Society, has recently been engaged in an attempt to place our knowledge of this subject upon a sounder basis by investigating in detail some of the grounds in the neighbourhood of Plymouth, including important fishing grounds, with reference to the nature of the sea-bottom at each locality, and the whole assemblage of animals found there. Detailed charts are being prepared to exhibit the variations which take place from point to point. No attempt has previously been made to study fishing grounds with such thoroughness, having regard not only to the fishes, but to the whole collection of animal life which forms the basis of the food upon which the fishes exist. The investigation, which has involved a large amount of dredging and trawling, as well as the identification of the numerous species captured, has been carried out by Mr. E. J. Allen, the Director of the Plymouth Laboratory.

THE principles upon which long-period weather forecasts are made in India were described in a recent number of NATURE (November 26, p. 87). In connection with this subject it is interesting to note that the official forecast of the cold-weather rains in Northern and Upper India has just been published. According to the Calcutta correspondent of the *Times*, the conclusions drawn are that the winter rains in Upper India (from December to February) will very probably be at least normal, and that they may be in moderate excess. It is probable that the winter precipitation in the Gangetic plain will be about normal, and very probable that it will not be above normal. It is very probable that the rainfall of the next four months will be slightly defective in Assam and perhaps in Bengal. It is, on the whole, very probable that the rainfall in Central India and the Central Provinces will not be above the small normal of the period, and may be below it. The general inference is that the indications are to some extent conflicting, but that, on the whole, they are favourable in North-western India. The rainfall will hence be normal, or above it, in Upper India, and probably normal, or in slight to moderate deficiency, in North-eastern and Central India.

THE jubilee of the foundation of the Hakluyt Society was celebrated by a special meeting on Tuesday. During the fifty years the Society has been in existence it has issued numerous volumes containing the texts of travellers and voyagers in all parts of the world, which were previously unedited, untranslated, or unknown. By this action, remarked Sir Clements Markham, in his address to Tuesday's meeting, the Society has continued the work and strove to fulfil the aspirations of Richard Hakluyt. This great man, like the Society which bears his honoured name, is not so well known to the present generation, which owes so much to his labours, as he ought to be. Hakluyt saw the two great needs of his country. The first was caused by the ignorance of our seamen as regards the scientific branch of their profession. The second was the absence of records, and the way in which important voyages and travels were allowed to fall into oblivion. He strove, during a long life, with great ability and untiring perseverance, to remedy these evils; and the measure of success he attained justly placed his name among those of worthies who deserve well of their country. The great work of Hakluyt was the "Principal Navigations," in three folio volumes, a monument of useful labour. Shakespeare owed much to this work: Milton owed much more. Hakluyt died on November 23, 1616, in his sixty-fourth year.

THE U.S. Commission of Fish and Fisheries has just distributed a report, by Mr. B. W. Evermann, upon salmon investigations in the headwaters of the Columbia River, in the State of Idaho, in 1895, together with notes upon the fishes observed in that State in 1894 and 1895. The observations refer chiefly to the spawning habits of the redfish (*Oncorhynchus nerka*) and the Chinook salmon (*O. tschawytscha*). The proof that the large form of redfish is anadromous—that is, passes from the sea into fresh waters at certain seasons—appears to be conclusive, but the evidence that the small redfish comes up from the sea is not complete. It seems probable that both forms are anadromous; but, so far as the Idaho lakes are concerned, the small form has not been proved to be so. The redfish all die soon after spawning, while the young remain in the lakes and connecting waters for at least one year from the time when the eggs were spawned. The Chinook salmon also die soon after spawning; and the young appear to remain, for one year after the eggs are laid, near where they were hatched.

THE current number of the *Journal de Physique* contains a paper, by M. C. Duperray, on the optical properties of a glass cylinder in rapid rotation in a magnetic field. The experiments were undertaken to test the accuracy of Villari's result, that it requires quite an appreciable time (1/800 second) for a piece o flint glass to acquire the property of rotating the plane of polarised light when subjected to a magnetic field. Villari came to this conclusion, which is in direct contradiction to the results obtained by Bichat and Blondlot, and Curie by rotating a glass

cylinder between the poles of a magnet, with the axis of rotation perpendicular to the lines of force. If a beam of polarised light traversed the cylinder in the direction of the lines of force, Villari found that the rotation of the plane of polarisation decreased as the velocity of rotation of the cylinder increased, so as to become zero for a velocity of about 200 turns per second. He explained this result as being due to the molecules of the glass requiring a finite time to acquire the power of rotating the plane of polarised light. The author, in order to test the accuracy of Villari's deduction, has examined the optical properties of the rotating glass cylinder, and he finds the following :—The effect of centrifugal force on the glass is to virtually constitute it a bi-refringent body, with its axis parallel to the axis of rotation. Hence, unless the plane of polarisation of the incident light is parallel or perpendicular to the axis of rotation, the emergent light is elliptically polarised. The author, making use of this discovery, then arranged the plane of polarisation either parallel or perpendicular to the axis of rotation, and found that in a magnetic field of such a strength that the rotation was about 5°, so that the plane of polarisation of the emergent light remained practically either parallel or perpendicular to the axis of rotation, no change in the rotation produced by the magnetic field was produced by rotating the cylinder even at velocities exceeding 200 turns per second. Hence he concludes that the bi-refringence induced by the rotation may have vitiated Villari's results.

IN *Science* of May 1, 1896, Prof. Bigelow says :—"A scientific knowledge of the action of the currents in cyclones and anti-cyclones can be obtained only by a determined attack upon the physics of the upper levels of the atmosphere." Following out this idea, and owing to the impetus given to the systematic study of the clouds by the action of the Meteorological Conference at Munich in 1891, Mr. H. B. Boyer, the Weather Bureau observer at Key West, Florida, has published a pamphlet entitled "Atmospheric Circulation in Tropical Cyclones, as shown by the Movement of the Clouds." The observations were begun in 1891, and in the treatment of the data each storm is taken in its chronological order, while the different currents and the bearing of the centre are shown on diagrams. The conclusions as to the behaviour of the upper and lower clouds in tropical storms are, so far as they go, valuable, and agree, upon the whole, with those found to obtain in our latitudes.

Spelunca continues to publish accounts of cave exploration in various parts of the world. No. 7–8 of vol. ii. contains some good views of cliffs and caves in the Liparis, along with other interesting matter.

TWO publications of the Geological Survey of Alabama have come to hand. One is a very detailed description of the iron industry of that State; the other (*Bulletin* No. 5) is a preliminary report on the mineral resources of the Upper Gold Belt, with petrographical descriptions of the crystalline rocks.

PHYSICAL investigators and instrument makers will be interested to know that Prof. C. V. Boys contributes to the *Electrician* of December 11, the first part of a detailed description of the method of making and manipulating the fine quartz fibres for which his name is famous.

THE Belfast Naturalists' Field Club has issued, as an appendix to its *Proceedings*, a "Bibliography of Irish Glacial and Post-Glacial Geology," by R. Ll. Praeger. This contains a list of over 700 books and papers, varying in importance from a geological survey memoir to an anonymous letter to a local newspaper. A subject-index and a geographical index are added. It should prove of great value both to Irish and to "glacial" geologists; while in the thoroughness with which it has been compiled, and the method of cataloguing, it may serve as a model to all local bibliographers.

A DETAILED discussion of the meteorological conditions at Frankfurt a.M., from observations extending over thirty-six years (1857–92), has been completed by Dr. Julius Ziegler and Prof. Dr. Walter König, and is now published under the title "Das Klima von Frankfurt am Main" (C. Naumann). The observations, which were made under the auspices of the Physikalische Verein, have been subjected to a very careful analysis, and the results are expressed diagrammatically upon ten full-page plates and several figures in the text.

THREE local scientific societies have lately sent us reports comprising papers read at their meetings. In the *Transactions* of the Edinburgh Field Naturalists' and Microscropical Society (1894–96), we notice papers on Daubenton's Bat (*Vespertilio Daubentoni*), as observed and captured in Glen Dochart, Perthshire, the geology of Arran, trout and their influence in purifying water, the little Auk, poisonous plants, the habits of Gulls, popular delusions in natural history, and researches on snake poison, with special reference to the work of Dr. Cunningham, of Calcutta.—The *Transactions* of the Ealing Natural Science and Microscopical Society (1895–96) contain a descriptive list of the birds of the Lower Brent Valley, and abstracts of lectures on parasitic and saprophytic plants, the last stages of the Great Ice Age in the neighbourhood of Ealing, and the relation of man thereto, recent astronomical photography, the life-history of *Atypus piceus*, wild bees, the structure of flames, and others.—The portrait of Prof. Ramsay forms the frontispiece of the *Proceedings* of the Bristol Naturalists' Society, and is accompanied by a short biographical notice. Among the papers is one on the British Jurassic Brachiopoda, and another on some ancient British remains at Long Aston, Somerset.

LIMITS of space prevent us from doing more than refer to a few of the papers in the *Journal* and *Proceedings* of the Royal Society of New South Wales (vol. xxix.), received a few days ago. In an important paper Mr. Lawrence Hargrave describes his aeronautical experiments with cellular kites. Mr. G. H. Knibbs contributes a long account of the history, theory, and determination of the viscosity of water by the efflux method; and Dr. C. J. Martin gives the results of a detailed investigation of the physiological action of the venom of the Australian Black Snake (*Pseudechis porphyriacus*). The surviving refugees, in austral lands, of ancient antarctic life are considered by Mr. C. Hedley. The paper by Mr. H. C. Russell, on icebergs in the Southern Ocean, and that of Mr. Henry A. Hunt, on types of Australian weather, have already been noted in these columns. In a paper on the amount of gold in sea-water, Prof. Liversidge concludes that gold is present in the sea-water off the coast of New South Wales in the proportion of about ·5 to 1 grain per ton, or, in round numbers, from 130 to 260 tons of gold per cubic mile. The results, in a second paper on the removal of silver and gold from sea-water by Muntz metal sheathing, indicate that by keeping the metal in the sea for several years the proportion of gold increases, while that of silver decreases. Ethnologists will be interested in Dr. John Fraser's presentation of three myths about the Senga parroquet, showing how intimately Fiji and Samoa were connected in the minds of the early myth-makers. The subjects of other contributions to the volume are Australian vegetable exudations; notes on Antarctic rocks, collected by Mr. C. E. Borchgrevink; the great meteor of May 7, 1895; and fascine work in New South Wales.

THE additions to the Zoological Society's Gardens during the past week include a Grey Ichneumon (*Herpestes griseus*) from India, presented by Colonel Smythe; a Changeable Tree Frog (*Hyla versicolor*) from North America, two White's Tree Frogs (*Hyla caerulea*) from Australia, presented by Mr. F. E. Blaaw; two Maned Geese (*Chenonetta jubata*) from Australia, purchased.

OUR ASTRONOMICAL COLUMN.

"BUREAU DES LONGITUDES."—The *Annuaire* for the year 1897 is still as complete as ever, and is a necessary *vade mecum* to the astronomer, physicist, and chemist. Our readers are so familiar with the usual contents of this compact little volume, that we limit ourselves to summing up the chief alterations and additions. The table of minor planets has been completed up to September 7, 1896, the number of these bodies now amounting to 431. Cometary notices have been brought up to the year 1895, while several new values for double-star elements have been inserted. Among the articles, which are always of great interest, are three from the pen of M. F. Tisserand. The first is a masterly summary of our knowledge of the proper movement of the solar system; the second, on the fourth meeting of the International Committee for the completion of the photographic map of the heavens; and the third, on the labours of the International Commission on fundamental stars. M. H. Poincaré writes on the kathode and Röntgen rays. M. J. Janssen discusses some epochs in the astronomical history of planets, and the work done at the Mont Blanc Observatory during the present year. Several discourses are also included, namely, that delivered by M. A. Cornu at the funeral of M. Fizeau, and those delivered by M.M. Janssen, Lœwy, and Poincaré at the funeral of the late Director of the Paris Observatory.

"THE SYSTEM OF THE WORLD."—In a small pamphlet entitled "Unser Weltsystem" (Gustav Fock, Leipzig), Herrn A. F. Barth presents us with an essay on the movements of the bodies contained therein. Without going at all into mathematical reasonings, complicated by numbers, he limits himself to discuss in words the questions that arise. In this way a clear idea of the movements of the earth round the sun, and also those further movements due to perturbations, can be obtained. Not only are the earth's motions discussed, but those of the moon are also taken in hand. One may here, among other things, learn what are the causes which give us different lengths of days, months and years, and how these may be converted into one another. These and several other points are touched upon, and the author concludes with a few general remarks on the extent of space.

Another pamphlet (Gauthier-Villars et Fils, Paris) contains an exposition of the mechanical formation of a "Système du Monde," after a new theory by Lieut.-Colonel du Ligondès. M. L'Abbé Th. Moreux is the writer of the essay, and he introduces this new idea to us after a short summary of previous hypotheses, such as those of Laplace and Faye. Assuming that motions in space can take place in all directions, then if there exist spots around which these movements are to a certain extent symmetrical, and if such a region be more or less homogeneous, then disturbances will be equally symmetrical in every direction, and a nearly round mass will be formed. The next stage in the development of this mass is its change of shape from circular to lenticular. This is brought about by the particles circulating towards the interior of the mass, and therefore coming into collision with one another. With condensation the mass becomes less homogeneous, and the law of gravity becomes modified. A general deformation of all the orbits of the particles commences, and finally a lens-shaped mass is the result. A ring now begins to be formed, having its point of greatest density some distance from its centre. The values of gravity vary along a radius, being small at the centre, reaching a maximum some distance away, and finally vanishing. The point of maximum velocity coincides with the maximum value of gravity. The ring becomes now the centre of attraction of bodies lying near it. Stresses are set up and a rupture takes place, this ring being split into three parts. At a later epoch the conditions are such that another ring of small dimensions is formed; this forms a second maximum point of density on the flat disc, which eventually is ruptured. These rings finally condense and form the several planets. The theory accounts for the different densities, sizes, rotations, and velocities of the planets, and also for the cases of the satellites. Space forbids us, however, from going into this theory more in detail, but there are several good points about it which make it interesting.

"COMPANION TO THE OBSERVATORY."—This annual for the year 1897 contains the usual amount of useful information, and the arrangement remains as formerly. Mr. Denning gives the list of principal meteor showers for the year, but we are surprised to see that no additional information is given of those swarms which will be of special interest during the next year or two. Data for the total solar eclipse which will occur on January 21, 1898, in addition to the two annular eclipses in 1897, are given. An ephemeris for Jupiter's fifth satellite up to the middle of May also receives a place, but its accuracy is doubted, for, as Mr. Marth says, no recent measures have been made, so that the adopted daily rate of motion is based on measures made in 1892 and 1893. The variable star information is very full and complete; but, if we may venture to make a suggestion, the table giving the mean places for the year 1897 would be made more useful if the approximate periods were to be placed against each star.

BACTERIAL WATER PURIFICATION.

THE twenty-seventh annual report of the State Board of Health of Massachusetts for 1895 has just been issued. This is the eighth year that the valuable experimental work of the now famous Lawrence Experiment Station has been continued. Although no very remarkable novel features have been recorded in the practice of bacterial water purification, it is highly satisfactory to find that the previous important work of the station is fully confirmed by the investigations conducted during the past year. An interesting point to which attention is called is the tendency exhibited by sand-filters to increase in bacterial efficiency in proportion to their period of service. In support of this the working of the oldest experimental filter at the station, and one of those with the greatest effective size of sand grain, is cited. This filter in 1893, filtering at an average rate of 2,000,000 gallons per acre daily, had a bacterial efficiency equal to 96·75 per cent.; during 1894 its rate of filtration was 4,500,000 gallons per acre daily, and its bacterial efficiency reached 98·97 per cent., whilst in 1895, although working at approximately the same rate as in the previous year, its bacterial efficiency rose to 99·57 per cent. This increased bacterial efficiency, caused by greater length of service period, was considerably more marked in the case of filters constructed of medium coarse or coarse sands than with those in which medium fine sand was employed. It would be out of place in these columns to discuss the various technical questions dealt with in the report, but there is one point which is very clearly brought out, and which is of particular interest in connection with the controversy which has recently arisen over the bacterial examinations of the London water-supply. An attempt has been made more than once to discount the value attaching to early bacterial examinations of the London waters, which first exhibited the efficiency of the purification processes employed, on the ground that the samples for investigation were not collected direct from the filters but from the delivery pipes. It has been contended that the numerical results obtained from samples drawn from the mains do not represent the bacterial efficiency of the purification processes in operation at the works, and this contention is based upon the hypothesis that the bacteria present in the effluent multiply in the pipes before delivery. The examinations made at the Lawrence Experiment Station show that there is no foundation whatever for this supposition. Thus in the monthly averages of daily bacterial examinations made of the Lawrence water conducted over six months, we find the raw river water contained 7533 bacteria per cubic centimetre, the effluent taken direct from the filter 134, the reservoir outlet 119, and the samples taken from the City Hall tap 86 bacteria per cubic centimetre. These results are sufficiently striking and instructive, and require no further comment. Another point to which considerable interest attaches is the effect upon the total number of bacteria which appear upon a gelatine plate, produced by the time during which the latter is kept and the colonies counted. Thus a water-plate poured from raw river-water exhibited 913 colonies per cubic centimetre on the first day, after two days the number rose to 8613, after three days to 12,317, whilst after four days they numbered 15,017 per cubic centimetre. Similarly in a sample of the same water filtered, whilst only three colonies could be counted on the first day, 48 made their appearance after two days, 72 after three days, and 87 per cubic centimetre after four days. The bacteriological examination of water, it cannot be too frequently insisted upon, is surrounded with subtle pitfalls into which the unwary may very easily be decoyed, and if the method is to take its position as a scientific process, too much attention to the details upon which its accuracy depends cannot be expended. In conclusion, in the section devoted to bacteriological technique, we note the

introduction of a new word. Hitherto we have spoken of plate-cultivating a given water, but this expression we find cut down to "plating" a water; as, however, the general practice is now to substitute dishes for plates, we shall probably be reduced to the ugly phraseology of "dishing" a water.

G. C. FRANKLAND.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—At the Junior Scientific Club, on December 9, Mr. E. S. Goodrich read a paper on the "Evolution of the Ungulata," and Mr. E. C. Atkinson gave an account of some further experiments on rowing, exhibiting and describing also the improved form of his rowing indicator.

CAMBRIDGE.—All the graces which were non-placeted on December 10, were carried by considerable majorities. The professorship of Surgery has accordingly been suspended for one year, the professorship of Logic and Mental Philosophy is established, and the Sedgwick Memorial Museum of Geology will be built on the ground lately belonging to Downing College. At the same Congregation it was agreed to present to the Lord President of the Privy Council a memorial urging the necessity of legislation bearing upon secondary education.

Mr. Ernest Clarke, Hon. M.A., of St. John's College, Secretary of the Royal Agricultural Society, has been appointed the first Gilbey Lecturer in the History and Economics of Agriculture.

Mr. J. J. H. Teall, of St. John's, has been appointed an elector to the Professorship of Geology; and Dr. A. S. Lea an elector to the Professorship of Physiology.

THE Hamilton Court Building Company, consisting of friends of Columbia University, have purchased land in New York City, at a cost of two hundred thousand dollars, and will erect upon it, at a cost of one million dollars, a dormitory to accommodate 900 students of the University.

THE following are among recent announcements:—Dr. W. Valentiner, associate professor of astronomy at Heidelberg, to be full professor, and Dr. Knövenagel to be associate professor; Dr. P. Freiherr von Lichtenfels to be professor of mathematics in the Technical High School at Graz; Dr. W. Rothert to be associate professor of botany in the University of Kasan; Dr. Seitaro Goto to be professor of botany in the First High School at Tōkyō, Japan; Dr. Kepinsky to be associate professor of mathematics at the University of Krakau.

THE William Gossage Laboratories, just added to the Chemical Section of Liverpool University College, were formally opened on Saturday by Lord Derby, President of the College, in the presence of a large and representative gathering. The laboratories have been built and equipped at a cost of 7000*l.* by Mr. F. H. Gossage and his partner Mr. T. Sutton Timmis, as a memorial of the father of the former, the late Mr. Wm. Gossage, distinguished as a chemical investigator and inventor of chemical processes. An address was delivered by Prof. Ramsay on chemical education and the equipment of laboratories. A full report of the address and other speeches made upon the same occasion is given in the *Liverpool Courier* of Monday, December 14.

SIR P. MAGNUS, in the course of some remarks at the Norwood Technical Institute, on Wednesday of last week, reviewed the history of the polytechnic institutes in London and the provinces. He estimated the amount spent on evening teaching, exclusive of interest on capital outlay for buildings, at over 175,000*l.* a year. It was pointed out that the London institutes give facilities not only for technical but also for literary and general education, which are not obtainable on the same scale and on similar lines in any other capital in the world. The reason why in some other countries, especially in Germany and Switzerland, lads are better able to profit by the technical instruction of evening classes than they are in this country, is because the lads leave school at a later age and more generally attend continuation classes.

IT is very satisfactory to note that our political leaders have lately devoted themselves to expounding the connection of science with industry. Mr. A. J. Mundella, M.P., speaking at the Birmingham Municipal Technical School, on Friday last, on the subject of German competition, said he quite admitted that we had suffered loss from our past neglect, particularly in regard to the development of the new sciences and new discoveries, which Germany had adopted and developed in a marvellous manner. He instanced the growth of the colour trade in Germany. That industry was an English discovery, founded by a Birmingham man, and worked in Manchester. Yet English manufacturers, not for the want of money or want of enterprise, but from the want of knowledge, had allowed it to be exploited by Germany, and the trade, amounting to many millions a year, had almost entirely left this country.

IN the course of an address at the Battersea Polytechnic, on Wednesday in last week, the occasion being the distribution of prizes and certificates to evening students, Mr. John Morley, M.P., referred to a few points of importance to science and education. He remarked that those who had studied the education question seriously were aware that a London polytechnic was not the same thing as a German polytechnic. In German polytechnic institutions the students learned the highest, most important, and profoundest principles in connection with the scientific subject which they there studied. The main object in the London polytechnic institutes was a different one; it was that the craftsman, the man who made things and did things with the labour and skill of his hand, should have opportunities brought within his reach of training not merely in the mechanical details but in the principles and the basis of his work. It was difficult, however, it was impossible, to put scientific methods and spirit into the habits of people who had not already undergone a preliminary training. There was a direct connection between technical education and an improvement in their national system of secondary education which did not yet exist. He hoped that the Government before many weeks were over would lay before the House of Commons a scheme for the improvement of secondary education. Every one saw that a higher appreciation of science, of the technical arts, of the improvement of scientific research and investigation on the part of the great English manufacturers was of the very utmost importance. One very often heard of the workmen being complained of; but it was now being seen that the leaders and captains of industry, especially the employers and the heads of great manufacturing enterprises, must open their minds to the improving of scientific investigation and research and training, both for the heads of the enterprises as well as for those who had the actual conduct and the carrying of them out. When the sources of the successful competition against this country in certain branches of industry were investigated, he believed that competent men in trade who had examined the matter would say that one great source of the success of foreign competition, and especially of German competition, had been the existence in Germany for some years of an organised and systematic plan for technical education, technical education connected with the other branches of education; and he hoped that this country would speedily amend and reform its system. . . . A scheme was being framed for a Teaching University for London—a most important scheme. It was most desirable that this body, when it was established, should not be so constituted as to discourage the evening teaching and evening learning of such places as the Battersea Polytechnic. They should allow students from such institutions as this to be admitted by their examinations.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, December 11.—Prof. Ayrton, Vice-President, in the chair.—A paper on the applications of physics and mathematics to seismology was read by Dr. C. Chree. Prof. J. Milne has attempted to account for certain changes in the indications of spirit-levels and delicately suspended pendulums by the supposition that they are due to meteorological agencies, such as rainfall or evaporation. Thus he considers that a relative excess of moisture—say, on the west of an observatory—is equivalent to a surface load on that side tending to make the ground, on which the observatory rests, slope downwards from east to west. The author, by making the assumptions as to the physical state of the substance of the earth that it is a homogeneous, isotropic, elastic solid, has examined in as general a manner as possible the amounts of flexure which would be produced by different systems of loading. He points out that the alteration in the reading of such an instrument as

a spirit-level depends not only on the bending of the surface of the earth, but also on the attraction exerted by the load, which slightly alters the direction of "gravity." He shows that if ψ_1 is the alteration in level produced by the bending, and ψ_2 the alteration in the direction of gravity, then the ratio ψ_1/ψ_2 depends only on the elastic constants of the earth, and is quite independent of the shape and size of the loaded area. In the case of a material having the elasticity of steel $\psi_1/\psi_2 = 2$, for brass $\psi_1/\psi_2 = 5$, and for an incompressible material $\psi_1/\psi_2 = 11$. The author considers that this last value most truly represents what occurs in practice, and hence that the pressure effect is considerably larger than the gravitational effect. The pressure effect is worked out for the cases where the loaded area is a square, and a long narrow rectangle, and it is found that for a square of 100 metres side the effect, at a point one metre from one side, of loading the square with a layer of water one centimetre thick, is to alter the level by 0·0012 second of arc. For the case of a tidal river 100 yards wide, and for a rise of 5 metres, the effect on an observatory at 100 yards from the bank would be to alter the level by 0·1 second of arc. Hence the effect of an estuary or tidal river is likely to be much more marked than differential evaporation or rainfall. The author also considers the effects of the attraction of the sun and moon, producing as they must "tides" in the solid crust of the earth, on the reading of a level and the measured altitude of a star as obtained with an artificial horizon. Finally the author considers the light the measurements on the velocity of propagation of earthquake disturbances throw on the credibility of the hypotheses he has made us to the elastic constants of the earth. He shows that the two observed velocities of 2·5 and 12·5 kilometres per second would lead to values for Young's modulus, and the rigidity below those found in the case of iron; the bulk modulus, however, obtained is very high, and this he considers quite probable on account of the enormous pressure to which the earth's deep-seated material is subjected. Prof. Perry said he had thought of taking up the subject from an experimental point of view, and trying the effect of loading a large block of indiarubber. He had not had time to refer to the author's paper, in which the reasons were given for taking the earth as incompressible. He (Prof. Perry), however, thought that this assumption led to results in contradiction to actual observed facts. Prof. Milne had obtained results which, for want of any other explanation, he had been compelled to attribute to meteorological causes. The reason Dr. Chree had obtained so small a value for the effect of loading by surface water might be because he had assumed erroneous values for the elastic constants. If he took a value for Poisson's ratio such as we meet with in practice, the effects would be much larger. Prof. Darwin had also investigated the folding of the surface of the earth due to loading. The results obtained by the author with reference to the velocity of waves did not seem quite satisfactory. The small waves which were found, both at Berlin and the Isle of Wight, to precede the main waves coming from an earthquake in Japan were not accounted for. The wave velocity in an infinite mass of steel (a very elastic material) was about 6 kilometres per second, which was very different from 12·5 kilometres per second. The author had assumed such values for the elasticity as would give the correct velocity. The author in reply said that in applying the equations of elasticity to the earth's interior, unless the material were supposed nearly incompressible, one obtained values for the strains too large to be consistent with the fundamental mathematical hypothesis, that the square of strains are negligible. In the case of surface loading no such restriction was necessary, so far as the surface layers, at least, are concerned. The differences between the several numerical estimates for the ratio of the gravitational and pressure effects of a surface load were principally due to the differences in the hypothetical values ascribed to the rigidity. It was his wish to make it clear that the pressure and gravitational agencies treated in detail in the paper were not the only ones likely to affect the level; he had specially called attention to solar heating and possible direct influence of moisture on the foundations of buildings, &c. The reason why for the one wave velocity so much higher a value was obtained than that Prof. Perry calculated for steel, was solely the high value, 24 : 1, found for the ratio of Thomson and Tait's elastic constants m and n. He knew Prof. Darwin had treated of the phenomena met with in loose earth in some cases, but could not say whether this was what Prof. Perry referred to. He had himself once thought of attempting an application of what Prof. Karl Pearson termed the "equations of pulverulence," as treated in detail by Prof. Boussinesq, but had not done so, partly from a feeling of uncertainty as to their physical value. Supposing these equations satisfactory, they ought to give better results than the equations of elasticity when surface load was applied to a deep alluvial soil.—A paper on musical tubes, by Mr. R. T. Rudd, was, in the absence of the author, read by the Secretary. The author has examined a set of tubes ranging in length from 95 inches to 12 inches, made out of "1-inch" gas-tube. Having tuned these to a diatonic scale, he found that there was a very marked difference in the character of the sound of the long, the middle, and the short tubes. Commencing with the long tubes, the first two octaves have a full rich tone very similar to that of a church bell. They range from D of 145 vibrations per sec. to D of 580 vibrations. At about this point the tone changes from that of a church bell to one peculiar to tubes, the note also falls back in the scale more than a fifth, viz. to F♯ (360), the same tube giving two notes, to either of which the attention can be directed. In order to distinguish these different classes of sound produced by tubes, the author calls the tone corresponding to that of a church bell the "low grade," the next one the "middle grade," and that produced by short tubes (27 in. and under) the "high grade." At the junction between the high and middle grade there is a fall in the note of about an octave and a half. The following formula may be used for calculating the pitch of the note given by a tube: $V = DC/L^2$, where V = frequency, D = external diameter, L = length, and C is a constant which for iron tubes has the value 100×10^4, 62×10^4, or 22×10^4, according as the note belongs to the low, the middle, or the high grade. The author explains the effects by a consideration of the partial tones present and their effect on the ear. Prof. Rücker said he thought it a great pity that in England such confusion of nomenclature existed, so that partials were often called over-tones. He considered that the author had made an extremely ingenious attempt to explain the differences of pitch observed, this explanation apparently resembling that given by Prof. Everett to account for combination tones. The author explains the presence of a note of frequency 630, as being formed in the ear by the harmonies having frequencies of 1260, 1900, and 2600. He also explains the absence of lower partials having frequencies of 780, 390, and 140 by the supposition that they are so far removed from the "focus" as not to appreciably affect the ear. Another explanation of the presence of a note of frequency about 630 would, however, be the formation of a difference tone between the partials of frequency 780 and 140. Mr. Blaikley agreed with Prof. Rücker as to the vagueness of the terms often employed, and said that it appeared that in the "high grade" the note was caused by the first proper tone, in the "middle grade" by the second, and in the "low grade" by a difference tone produced by the fourth, fifth, and sixth proper tones. The distance of the nodes from the end of the tube was ·224 of the length, and not ·25, as the author states, and in the case of a tube clamped at the node, this difference in the position of the clamp would have a marked effect on the tone. A great distance in the tone was also produced by varying the hardness of the hammer. Prof. Ayrton said he had once investigated the behaviour of some tubes by analysing the note given out by means of a Helmholtz analyser. In the case of the tubes that gave a good note, it was found that the components were few and well-marked, while in that of the tubes which gave a bad note, the components were numerous and sometimes very ill-defined. The relative length, diameter, and thickness of the tube had a great influence on the tone.

Chemical Society, December 3.—Mr. A. G. Vernon Harcourt, President, in the chair.—The following papers were read: Constitution and colour, by A. G. Green. Colouring matters may be classified in two groups, viz.: (1) Colours whose leuco-compounds are not readily oxidised on exposure to air; (2) colours whose leuco-compounds are rapidly oxidised on exposure to air. It is shown further that the members of class 1 are all para-derivatives, whilst those of class 2 can all be represented as ortho-compounds.—Derivatives of α-hydrindone, by C. Revis and F. S. Kipping. The authors have studied α-hydrindone in order to determine whether its reactions are analogous to those of camphor, which it resembles somewhat in constitution; there is, however, a marked difference between the chemical behaviour of the two ketones.—Notes on nitration, by H. E. Armstrong.—3′-Bromo-β-naphthol, by

H. E. Armstrong and W. A. Davis. 3′-Bromo-β-naphthol is prepared by digesting 1 : 3′-dibromo-β-naphthol with hydriodic acid.—Derivatives of nitro-β-naphthols, by W. A. Davis.—Morphotropic relations of β naphthol derivatives, by W. A. Davis. The author shows that a marked crystallographic relation exists between a number of 1 : 2 and 1 : 3′ : 2 naphthalene derivatives; although the crystalline systems of the various substances examined are not the same, yet the axial ratio $c : b$ is nearly the same in all.—Researches on tertiary benzenoid amines, by Miss C. de B. Evans. A number of sulphonic acids of benzenoid amines have been prepared; it is shown that although orthosulphonic acids are readily obtained from aniline derivatives, there is usually extraordinary difficulty in preparing metasulphonic acids.—On the circumstances which affect the rate of solution of zinc in dilute acids, with especial reference to the influence of dissolved metallic salts, by J. Ball. The effects on the rate of solution of zinc in dilute acids of (1) variations of concentration of the acid; (2) previous special treatment of the acid; (3) variations of temperature; (4) variations of pressure; (5) variations of the surface condition of the zinc; (6) admixture of other metals with the zinc; (7) performance of the solution in vessels of different materials; and (8) addition of various substances to the acid solution, have been studied. It is of interest to note that the addition of foreign salts to the solution always accelerates the dissolution of the zinc.—The oxidation of ferrous sulphate by sea-water, and on the detection of gold in sea-water, by E. Sonstadt. The author shows that by prolonged agitation of half-a-gallon of sea-water with twenty grains of mercury, an appreciable quantity of gold is taken up by the mercury.

Mineralogical Society, November 17.—Annual Meeting; Dr. Hugo Müller, F.R.S., in the chair.—The balance-sheet for the year ending December 31, 1895, was presented, and showed that the state of the finances of the Society continues to be very satisfactory. The number of members is now 130. Two numbers of the journal have been issued during the past year, including an index of authors and subjects for the ten volumes of the journal which have now been published. The Council were able to congratulate the Society upon the continued steady sale of the journal. Mr. Thomas Henry Holland, superintendent of the Geological Survey of India, Calcutta, was elected a member of the Society. The following papers were then read: Notes on Zirkelite and Derbylite, by E. Hussak and G. T. Prior; some crystals of iron pyrites from Cornwall, by A. Hutchinson; crystallographic notes on Zinckenite, Wolfsbergite, Plagionite, Stephanite, Enargite, and Anglesite, by L. J. Spencer; the discovery of Prehnite in Wales, by T. J. Harrison.—It was subsequently announced that the following gentlemen had been duly elected as Officers and Council of the Society for the ensuing year: President, Prof. N. S. Maskelyne, F.R.S.; Vice-Presidents, Rev. S. Houghton, F.R.S., and Dr. Hugo Müller, F.R.S.; Treasurer, Mr. F. W. Rudler; General Secretary, Mr. L. Fletcher, F.R.S.; Foreign Secretary, Prof. J. W. Judd, F.R.S.; ordinary members of Council, Mr. W. Barlow, Prof. A. H. Church, F.R.S., Prof. H. A. Miers, F.R.S., and Mr. W. J. Pope; in addition to the following members not requiring re-election: Prof. Geikie, Messrs. Harker, Hutchinson, Kitto, Prof. Lewis, Lieut.-General McMahon, Messrs. Tutton and Watts.

Geological Society, November 18.—Dr. Henry Hicks, F.R.S., President, in the chair.—On *Cycadeoidea gigantea*, a new cycadean stem from the Isle of Portland, by A. C. Seward. The specimen described by the author was discovered a short time since in one of the Purbeck dirt-beds, and is now in the Fossil Plant gallery of the British Museum. A comparison of this fossil with recent cycads and ferns brought out many points of close agreement with the former, and as regards the structure of the ramenta, evidence was afforded of an interesting survival of the closer resemblance which formerly existed between cycadean and fern-like plants. The stem has been named *Cycadeoidea gigantea*.—The fauna of the Keisley limestone (Part ii., conclusion), by F. R. C. Reed. The author described the ostracoda, brachiopoda, mollusca, echinodermata, and actinozoa of the Keisley limestone. He gave a list of fossils from the limestone, and indicated those species which occurred in the limestone of Kildare, the *Leptæna*-limestone of Sweden, and Stage F of the East Baltic provinces. As a result of his researches he concluded that the fauna had a thoroughly ordovician facies; that it was closely comparable with that of the limestone of the Chair of Kildare, and of the *Leptæna*-limestone, and less closely with that of Stage F of the East Baltic provinces; that its palæontological features pointed to its stratigraphical position being at the base of the Upper Bala, and that it must be regarded as the locally thickened development of a bed which was elsewhere in Great Britain very thin, or entirely absent, or represented by beds having different lithological characters and a different fauna; and that the fauna had certain unique characters which marked it off from all other known assemblages of fossils in Great Britain.

Royal Microscopical Society, November 18.—Mr. A. D. Michael, President, in the chair.—The Secretary read a note, from Mr. E. M. Nelson, on the Hugh Powell Microscope in the Society's collection. A discussion ensued, in which Mr. Ingpen, Mr. Vezey, Prof. Bell, Mr. Beck, and the President took part.—Lieut.-Colonel H. G. F. Siddons exhibited and described a portable cabinet for mounting apparatus.

Linnean Society, November 19.—Mr. A. D. Michael, Vice-President, in the chair.—Dr. D. Morris, C.M.G., exhibited from the Royal Gardens, Kew, the inflorescence of *Pterisanthes polita*, a singular species of the Vine Order (Ampelideæ), received in 1894 from Mr. H. N. Ridley, of Singapore, and now in flower for the first time in Europe. *Pterisanthes* is closely allied to *Vitis*, but shows in a more interesting manner the true nature of the tendrils, and a special modification of the receptacle suggested only in *Vitis macrostachya*. Dr. Morris also exhibited dried flower-stems of the Australasian twin-leaved Sundew (*Drosera binata*, Labill.), received at Kew from the Sheffield Botanic Garden. In this instance the stems were 3 feet 6 inches high, bearing about thirty to fifty large pure white flowers, nearly 1 inch across. The plant grown in gardens in this country is seldom more than 9 inches to a foot high.—Mr. W. G. Ridewood read a paper on the structure and development of the hyobranchial skeleton and larynx in *Xenopus* and *Pipa*. The conclusions were drawn that *Pipa* and *Xenopus* are descended from tongue bearing ancestors, and that in spite of the anatomical differences between the two genera, the sub-order Aglossa is a natural one.—A paper was then read by the Rev. T. R. Stebbing, F.R.S., "On the collection of Amphipoda in the Copenhagen Museum." Some of the more striking rarities were described, together with a few of a less uncommon type. The collection being cosmopolitan, the opportunity was taken of bringing into notice certain other new or insufficiently known forms received from Prof. Haswell, of Sydney, N.S.W., and from Mr. G. M. Thompson, of Dunedin, N.Z. The range of the various specimens described extends from Cuba to Ceylon; from the North Atlantic to the South Pacific; from the western coast of Scotland to the eastern coast of Australia and New Zealand. Nine genera and ten species were discussed, six of each being new.

Zoological Society, December 1.—Sir W. H. Flower, K.C.B., F.R.S., President, in the chair.—Mr. R. E. Holding exhibited and made remarks on a three-horned fallow deer's head and a malformed head of a roebuck.—Mr. H. E. Dresser exhibited and made remarks on a specimen of Pallas's willow-warbler (*Phylloscopus proregulus*), shot at Cley-next-the-Sea, Norfolk, on October 31, 1896, being the first instance of the occurrence of this bird in Great Britain.—Dr. Forsyth Major gave an account of the general results of his zoological expedition to Madagascar in 1894–96. Amongst the more important results attained by Dr. Major was the discovery of remains of a new fossil monkey (*Nesopithecus*), forming the type of a new family of Quadrumana, and of about twenty new species of living mammals, several of these belonging to new genera. A very fine series of bones of the extinct Æpyornithes obtained by Dr. Major would enable some nearly complete skeletons of this group to be put together for the first time.—A communication was read from Mr. Stanley S. Flower, containing an annotated list of all the reptiles and batrachians known to occur in the Malay Peninsula and on the adjacent islands. A new species of gecko (*Gonatodes penangensis*) was described, and original observations relating to the distribution, variation, and habits of known species were added, especially with regard to the tadpoles of various batrachians.—Mr. G. A. Boulenger, F.R.S., read descriptions of some new fishes from the Upper Shiré River, British Central Africa, based on specimens collected by Dr. Percy Rendall, and presented to the British Museum by Sir

Harry Johnston, K.C.B. The present collection contained examples of fourteen species, of which five were now described as new to science.—A second communication from Mr. Boulenger contained remarks on the lizards of the genus *Eremias*, section *Boulengeria*.—Mr. R. Lydekker, F.R.S., gave an account of an apparently new deer from North China, living in the menagerie of the Duke of Bedford, at Woburn Abbey, to which he proposed to assign the name *Cervus bedfordianus*.—The Secretary read a communication from Mr. A. J. North, of the Australian Museum, Sydney, containing an account of a cuckoo in the Ellice Islands (*Eudynamys taitensis*), which appears to lay its eggs in the nest of a tern (*Anous stolidus*).—The Rev. T. R. R. Stebbing communicated a paper by Dr. H. J. Hansen, of the Copenhagen Museum, on the development and the species of the Crustaceans of the genus *Sergestes*.

Entomological Society, December 2.—Dr. Sharp, F.R.S., Vice-President, in the chair.—Dr. Sharp exhibited the series of Longicorn Coleoptera of the genus *Plagithmysus* from the Hawaiian Islands, of which a preliminary account had recently been given by him elsewhere. He said that these examples were the result of Mr. Perkins' work for the Sandwich Islands Committee, and afforded a fair sample of his success in the other orders, which would be found to have completely revolutionised our knowledge of the entomological fauna of these islands. He stated that Mr. Meyrick had recently informed him that the *Geometridæ* would be increased from six species to forty-four, and that the genus *Plagithmysus* showed an almost equal increase; and that the working out of the specimens was very difficult, owing to the variability of the species and to their being closely allied.—Mr. Malcolm Burr exhibited a specimen of a cockroach, *Pycnoscelus indicus*, Fabr., taken in a house at Bognor, Sussex. He said this was the first record of the occurrence of the species in England. According to De Saussure, it was distributed throughout India, Ceylon, Mexico, and the United States.—Mr. F. Crowley exhibited a remarkable variety of *Abraxas grossulariata* taken in a garden at Croydon last summer.—Mr. Tutt exhibited some Micro-Lepidoptera from the Dauphiné Alps. Several specimens of *Psecadia pusiella*, Röm., showing considerable difference in the width of the black zigzag band crossing the centre of the forewings longitudinally. The species was taken at La Grave, in a gully at the back of the village. A large number of specimens were secured, chiefly resting on the trunks and branches of two or three ash and willow trees growing on the bank at the side of the gully. A few specimens, however, were obtained drying their wings on the grass on the bank, but Mr. Tutt stated that he failed to find pupa-cases. Mr. Tutt also exhibited specimens of a "plume" which had been named *Leioptilus* (*Alucita*) *scarodactyla*. He also exhibited specimens, from Le Lautaret, of *Gelechia spurriella*, *Sophronia semicostella*, *Pleurota pyropella*, *Œcophora stipella*, and *Butalis fallacella*. The latter were chiefly interesting from the fact that they were taken at an elevation of about 8000 feet.—Lord Walsingham, F.R.S., read a paper entitled, "Western Equatorial African Micro-Lepidoptera." A discussion ensued, in which Dr. Sharp, Herr Jacoby, and others, took part.

CAMBRIDGE.

Philosophical Society, November 9.—Mr. F. Darwin, President, in the chair.—"On the Nature of the Röntgen Rays," by Prof. Sir G. G. Stokes. In this communication the author explained the views he had been led to entertain as to the nature of the Röntgen rays, and to a certain extent the considerations which had led him to those conclusions. As Röntgen himself pointed out, the X-rays have their origin in the portion of the wall of the Crookes' tube on which the so-called kathodic rays fall, and it is natural that notions as to the nature of the X-rays should be intimately bound up with those entertained as to the nature of the kathodic rays. Two different views have been adopted on this question. Several eminent German physicists hold that the kathodic rays are essentially a process going on in the ether, the nature of which nobody has been able to explain; and that if any propulsion of molecules from the kathode accompanies them, it is merely a secondary phenomenon. The other view is that the kathodic rays are not proper rays at all, but that they are essentially streams of molecules. The author expressed the fullest conviction that the kathodic rays are no mere process going on in the ether, but that the propulsion of molecules is of the very essence of the phenomenon; only it is to be remembered that the molecules are not to be thought of as acting merely dynamically, by virtue of their mass and velocity; they are carriers of electricity; and it would seem to be mainly to this circumstance that some at least of their effects are due. He indicated what he believed to be the true answers to the objections of those who regard the kathodic rays as processes in the ether; and adopting the theory that they are streams of molecules explained how, in his opinion, this theory, taken in connection with the more salient features of the X-rays to which the kathodic rays give birth, leads us to a theory of the nature of the X-rays. Everything points to the X-rays as being, like rays of light, some process going on in the ether, and sufficient indications of their polarisation appear to have been obtained (at least when those indications are taken along with the undoubted polarisation of the Becquerel rays with which they have so many properties in common) to refer the Röntgen as well as the Becquerel rays to a disturbance transverse to the direction of propagation. The absence of refraction, which is so remarkable a feature of the X-rays, suggests that their progress through ponderable matter takes place by vibrations in the ether existing in the interstices between the ponderable molecules; a view which, if correct, leads incidentally to a somewhat novel view as to the mechanism of the refraction of light. The absence, or almost complete absence, of diffraction and interference of the X-rays leads to one of two alternatives—either that they are of excessively short wave-length, or that they are non-periodic or only very slightly periodic, the X-light being on the latter supposition regarded as a vast succession of independent pulses analogous to the "hedge-fire" of a regiment of soldiers. According to the author's view, each electrically charged molecule on arrival at the target gives rise to an independent pulse, and the vastness of the number of pulses depends on the vastness of the number of molecules in even a minute portion of ponderable matter.—"On the Contact Relations of certain Systems of Circles and Conics," by Mr. W. McF. Orr.—"On certain cases of discharge in vacuo, and on the zigzag path of Lightning," by Mr. J. Monckman.

PARIS.

Academy of Sciences, December 7.—M. A. Cornu in the chair.—Pleurisy in man studied by means of the Röntgen rays, by M. Ch Bouchard. The existence of pleurisy in the human subject is very clearly indicated by the Röntgen ray shadows, but the method offers no advantages over the ordinary clinical diagnosis.—On the composition of the gases which are evolved from the mineral waters of Bagnoles de l'Orne, by MM. Ch. Bouchard and Desgrez. The gas contained traces of helium, 4·5 per cent of argon, 5·0 per cent. of carbon dioxide, the remaining 90·5 per cent. being nitrogen.—The theory of the confluence of the lymphatics and the morphology of the lymphatic system of the frog, by M. L. Ranvier.—On the quaternary elephants of Algeria, by M. A. Pomel. In the two quaternary geological horizons six species of elephant have been found, the distinguishing characteristics of which are described.—The quaternary rhinoceri of Algeria, by M. A. Pomel.—Observations on the total solar eclipse of August 9, 1896, made in Japan by M. H. Deslandres.—Optical analysis of urine, and the exact estimation of proteids, glucosides, and saccharoid non-fermentable materials, by M. Fr. Landolph.—Germination of the spores of the truffle, by M. A. G. Grimblot.—Modification of a fundamental principle relating to imaginary quantities, by M. L. Mirinny.—An air compressor with two cylinders, by M. J. Niffre.—Comparison of the observations of Vesta with the tables, by M. Leveau.—On a class of paraboloïds, by M. A. Mannheim.—On the problem of Dirichlet and the fundamental harmonic functions attached to a closed surface, by M. Le Roy.—On the equations representable by three linear systems of points, by M. Maurice d'Ocagne.—The construction of standard plates for the optical measurement of small air thicknesses, by MM. A. Pérot and Ch. Fabry.—On the property of discharging electrified conductors communicated to gases by the X-rays by flames and by electric sparks, by M. Emile Villari. A reply to the claim for priority in this subject by M. E. Branly.—On lithium nitride, by M. Guntz. It is practically impossible to prepare lithium nitride in a pure state, as it exerts a solvent action upon every substance used as a containing vessel.—On the heat of formation of selenic acid and some selenates, by M. René Metzner. Measurements are given for the heat of neutralisation of seleni

acid with soda, potash, baryta, lead oxide, and silver oxide; and of the heat of formation of the various hydrates.—Estimation of phosphorus in the ashes of coal and coke, by M. Louis Campredon. It is shown that the whole of the phosphorus cannot be extracted from the ash even after a very prolonged heating with hydrochloric acid. Fusion with alkaline carbonates of the residue left after extraction with acid always gives a further amount of phosphate, which is the larger the longer the ash has been ignited.—Analysis of commercial copper by the electrolytic method, by M. A. Hollard. Details are given of the method employed for the exact estimation of the copper in crude coppers.—On ozone and the phenomena of phosphorescence, by M. Maurice Otto. Most organic substances are capable of giving rise to phosphorescence when placed in contact with ozone. The luminosity produced with ordinary distilled water is shown to be due to the presence of minute quantities of organic matter.—On the new bread for military purposes, by M. Balland.—Researches on the modifications of nutrition in cancerous subjects, by MM. Simon Duplay and Savoire. The alkaloidal substance isolated by M. Griffiths, in 1894, from cancerous urines, would appear to be due to the introduction of foreign micro-organisms; when the cancerous growth is in a part of the body naturally aseptic, no such substance can in general be found in the urine. An alkaloidal substance, differing in its reactions from that described by Griffiths, was, however, present in one case of sarcoma.—On a new method of collecting the venom of serpents, by M. Paul Gibier. It has been found that after suitable arrangements have been made for holding the snake and collecting the venom, the serpent refuses to emit a single drop of the venom. This difficulty is overcome by stimulating the venom glands and neighbouring muscles with a weak alternating current, when, in a few seconds, the glands are completely emptied.—Use of the grisometer in the medico-legal examination for carbon monoxide, by M. N. Gréhant. The gas is extracted by the aid of acetic acid and the mercury pump, and the carbon monoxide determined in the gas mixture by means of the grisometer.—On the development of some annelids, by M. Auguste Michel.—Observations on the rhizoctone of the potato, by M. E. Roze.—Destruction of *Heterodera Schachtii*, by M. Willot.—The endomorphic transformations of the granitic magma of Ariège, in contact with limestones, by M. A. Lacroix.—Artificial reproduction of pirssonite, northupite, and gaylussite, by M. A. de Schulten.—The Upper Jurassic strata in the neighbourhood of Angoulême, by M. Ph. Glangeaud.

DIARY OF SOCIETIES.

THURSDAY, DECEMBER 17.

ROYAL SOCIETY, at 4.30.—On the Dielectric Constant of Liquid Oxygen and Liquid Air: Prof. Fleming, F.R.S., and Prof. Dewar, F.R.S.—On the Effect of Pressure in the Surrounding Gas on the Temperature of the Crater of an Electric Arc: Correction of Results in former Paper: W. E. Wilson, F.R.S., and Prof. FitzGerald, F.R.S.—Influence of Alterations of Temperature upon the Electrotonic Currents of Medullated Nerve: Dr. Waller, F.R.S.—Subjective Colour Phenomena attending Sudden Changes of Illumination: S. Bidwell, F.R.S.—On the Occurrence of Gallium in the Clay-Ironstone of the Cleveland District of Yorkshire: Prof. Hartley, F.R.S., and H. Ramage.—On some Recent Investigations in Connection with the Electro Deposition of Metals: J. C. Graham.

LINNEAN SOCIETY, at 8.—On the Chalcididæ of the Island of Grenada: Dr. L. O. Howard.—On the Development of the Ovule of Christisonia, a Genus of the Orobanchæ: W. C. Worsdell.

CHEMICAL SOCIETY, at 8.—On the Experimental Methods employed in the Examination of the Products of Starch-hydrolysis: on the Specific Rotation of Maltose and of Soluble Starch; on the Relation of the Specific Rotatory and Cupric-reducing Powers of Starch-hydrolysis by Diastase: Horace T. Brown, F.R.S., Dr. G. H. Morris, and W. H. Millar.

ROYAL STATISTICAL SOCIETY, at 5.30.

FRIDAY, DECEMBER 18.

EPIDEMIOLOGICAL SOCIETY, at 8.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Wells, and Well-Sinking: John W. Kitchin.

SUNDAY, DECEMBER 20.

SUNDAY LECTURE SOCIETY, at 4.—Creatures of Other Days: Rev. H. N. Hutchinson.

TUESDAY, DECEMBER 22.

ROYAL INSTITUTION.—Use of Liquid Air in Scientific Research (before H.R.H. the Prince of Wales): Prof. Dewar, F.R.S.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Steel Skeleton Construction in Chicago: E. C. Shankland.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Alterations of Personality; A. Binet, translated by H. G. Baldwin (Chapman).—The Cell in Development and Inheritance: Dr. E. B. Wilson (Macmillan).—Second Annual General Report upon the Mineral Industry of the United Kingdom of Great Britain and Ireland for the Year 1895: Dr. C. le Neve Foster (Eyre and Spottiswoode).—Light as the Interpretation of the Law of Gravity: A. M. Cameron (Sydney, Angus and Robertson).—London University Guide and University Correspondence College Calendar, 1895–7 (Clive).—Hygiene for Beginners: Dr. E. S. Reynolds (Macmillan).—Compressed Air Illness: Dr. E. H. Snell (Lewis).—Roentgen Rays and Phenomena of the Anode and Cathode: E. P. Thompson (Ypsun).—Knowledge, Vol. xix (326 High Holborn).—Studies in the Morphology of Spore-producing Members: Prof. F. O. Bower. II. Ophioglossaceæ (Dulau).—Die Leitfossilien: Dr. E. Koken (Leipzig, Tauchnitz).—Elementary Non Metallic Chemistry: S. R. Trotman (Rivington).—The Fauna of British India, including Ceylon and Burma. Moths, Vol. iv.: Sir G. F. Hampson (Taylor and Francis).

PAMPHLETS.—Die Seen des Salzkammergutes und die Österreichische Traun: Dr. J. Müllner (Wien, Hölzel).—Die Abfluss-und Niederschlagsverhältnisse von Böhmen, &c.: Dr. A. Penck (Wien, Hölzel).—Atlas der Österreichischen Alpenseen, i. Liefg.: Dr. F. Simony and Dr. J. Müllner (Wien, Hölzel).—Ditto, ii. Liefg.: Dr. E. Richter (Wien, Hölzel.—The Results of the Use of Tuberculin in the Castlecraig Herd: J. Wilson (Edinburgh, Johnston).

PETROLEUM.

Petroleum: a Treatise on the Geographical Distribution and Geological Occurrence of Petroleum and Natural Gas; the Physical and Chemical Properties, Production and Refining of Petroleum and Ozokerite; the Characters and Uses, Testing, Transport, and Storage of Petroleum Products; and the Legislative Enactments relating thereto; together with a Description of the Shale Oil and allied Industries. By Boverton Redwood, F.R.S.E., F.I.C., Assoc.Inst.C.E., assisted by G. T. Holloway, Assoc.R.Coll.Sc., F.I.C., and others. 2 vols. 4to. 900 pp. (London: C. Griffin and Co., Ltd., 1896.)

Le Pétrole, l'asphalte et le bitume, au point de vue géologique. By A. Jaccard. Professeur Geologie à l'Académie Neuchâtel. 1 vol., 8vo., 292 pp. (Paris: F. Alcan, 1896.)

Petroleum: its Development and Uses. By R. Nelson Boyd, M. Inst. C.E. 1 vol. 8vo, 85 pp. (London: Whittaker and Co., 1896.)

As frontispiece to his first volume, Mr. Redwood has adopted a map of the world; and thereupon are indicated by red spots, the known localities of the occurrence of petroleum: so treated, only a few parts of the map remain undotted, and these are mostly those which, in the world, are either permanently ice or ocean-covered, or those which, such as Central Asia, Central Africa, and Central Brazil, are still but little explored. The universality, far from being confined to the geography of petroleum, is one of the main distinguishing features of this unique subject: the chemistry, geology, mining, technical applications, and legal and fiscal aspects, all demand, for their due elucidation, the most experienced experts, inasmuch as each of these aspects is of a quite special character, a peculiarity which, in its turn, arises from the fundamental fact that petroleum is unlike anything else among the world's chief products.

To write, or to compile, a comprehensive text-book on petroleum demands, therefore, an acquaintance with dissimilar subjects, and with varying walks of life, very rarely centred in one individual. The present work is and will ever remain remarkable as the production of a man whose scientific attainments, and whose relation to the petroleum industries, were such that he, probably better than any other living man, was fitted to undertake the task.

But while the qualifications of Mr. Redwood singularly well fitted him for attacking a problem which even the German had not attempted, the inherent difficulties of compiling this treatise must be prominently kept before the mind in forming a judgment as to the quality of the author's work, and due allowance must be made for places where, to this geologist or to that chemist, to this inventor or to that lawyer, it might seem that the elaboration had been too restricted, or the facts presented too few. Certainly a sincere tribute must be paid to the great industry displayed in the production of this work, to the careful selection of its facts, to the eminent sense of proportion shown in the marshalling of the latter, to the pure and lucid style, and especially to the wonderful fairness and judgment shown in briefly indicating the views of the principal disputants in the more contentious regions of its scope. The work contains a vast volume of information, the errors are very few indeed, and to those familiar with the busy life of the author in the very vortex of petroleum matters, it will not be a matter of surprise to learn that the work is, whether treating of new petroleum fields, new methods of drilling, recent improvements in testing, or fresh legal enactments, modern in every sense of the word.

Though in an encyclopædic work of this kind originality is hardly expected, and is perhaps out of place, the author carries a curious, quite Plato-like, shrinking from the revealing of his individuality, to an unnecessary pitch: indeed, most readers will have to confess to some disappointment in being unable to get at Mr. Redwood's own opinion on most of the debatable points connected with petroleum. Thus, Section iv., "The Origin of Petroleum and Natural Gas"—one of the least satisfactory of the eleven sections into which the work is divided, is summed up in the following words:

"Probably, on the whole, the Höfer-Engler views at present have the largest number of adherents, and in respect, at any rate, to certain descriptions of petroleum, are the most worthy of acceptance. At the same time, a careful study of the subject leads to the conclusion that some petroleum is of vegetable origin, and it therefore follows that no single theory is applicable to all cases."

Here, and especially also in the section devoted to liquid fuel, there seems to be too much quoting of "authorities," and too little critical examination of the, not infrequently, intrinsically worthless, "views" which, because emanating from the high-placed learned, have been allowed to obscure the subject: Mr. Redwood would have done good service in pruning away some of these. Two of the most valuable of the sections are those dealing with the "Geological and Geographical Distribution of Petroleum" and with the "Testing of Crude Petroleum and Shale Oil Products, Ozokerite and Asphalt," respectively. In the first of these Mr. Redwood has introduced a series of most carefully drawn maps and sections, many of these being original, and at any rate so in the forms now presented: the maps, in fact, constitute one of the most valuable features of the work, being the kind of map brought forward by the man who has visited the locality personally. As to the matters dealt with in the second of the sections mentioned above, Mr. Redwood is, of course, *facile princeps*, and it cannot fail to be a source of justifiable pride to him to see how much he has individually contributed to modern methods of testing petroleum. Equally (in conjunction with Sir F. Abel) in the flash-point apparatus, in the viscosimeter, and lately in the flame-cap apparatus, used for the detection of dangerous amounts of hydrocarbon gases in tank-ships and elsewhere, and in many other ways, the technical development of petroleum owes much to his labours; much more than he has allowed himself, with characteristic modesty, to indicate here.

The text is accompanied by over 300 illustrations, all most carefully revised and examined; those dealing with drilling implements being particularly serviceable.

It may be said generally that any one mastering the work would have a very competent knowledge of the subject, and one which he could not obtain from any other single source.

To summarise, it must be allowed (1) that a text-book upon petroleum—at once comprehensive and authoritative—was greatly needed; (2) that there was hardly any one capable of compiling such a work; (3) that Mr. Redwood has most successfully essayed and accomplished the task by the production of this most excellent text-book.

Unlike Mr. Redwood's work, that of Prof. Jaccard is concerned solely with the geology of petroleum, though the geology is of that wide order that it embraces such subjects as the origin of petroleum and of natural gas, and the causes of "bituminisation."

The study of the various conditions under which petroleum occurs in nature, is remarkably clearly written and is, moreover, illustrated by many admirable little semi-diagrams, thoroughly French in character, and truly luminous to the text: the work is, however, marred by the narrowness of view, displayed in the selection of the sources drawn upon, by the not infrequent antiquity of these latter, and by the only too obvious circumstance that for many of the localities, whose petroliferous peculiarities are described, the author only knew the facts at second-hand. Thus the account given of the occurrence of Galician petroleum and of the industry founded thereupon, is ridiculously brief; its inaccuracies at once stultifying also the author's table showing the occurrence of petroleum in strata of various ages. Transylvanian petroleum, including the interesting deposits about Soosmezo, is, apparently, not even mentioned, while the Roumanian deposits, much less important than those of Austria-Hungary, are described at some length—or, rather, M. Coquand's reports upon them are abstracted at some length. From the above it will be gathered that that study so much needed at the present moment, viz. a critical comparison of the petroliferous rocks of the Carpathians, has not been attempted by the author.

Naturally, when treating of the Jura, Vosges, Hanoverian, &c., petroleum localities, subjects to which he has devoted individual attention, Prof. Jaccard speaks with unquestionable authority, and this is the most valuable part of the book.

The author seems to have attempted to put forth his greatest strength in the chapters dealing with the origin of petroleum and its conditions of occurrence in the rocks, and the causes of these conditions. Though he admits a vegetable origin for certain petroleums, he considers, largely influenced to this opinion by his studies of the fossils of the Jura deposits, that a bituminisation of certain animal (especially molluscan) remains may be fairly demonstrated.

In spite of the fact that the work of French geologists is too exclusively referred to, while the work of others is often ignored, yet the book is an eminently clear and readable one; and, regard being had to the existing works, treating of the geology of petroleum, an English translation would undoubtedly be useful at the present time.

It may be noted that, prefixed to the work, there is an account of the life and work of Prof. Jaccard (died January 5, 1895).

In Mr. Boyd's readable book of eighty-five short pages a well-known petroleum-expert glances rapidly over the whole range of the subject for the benefit, primarily, of those who wish to glean some smattering of petroleum-lore. The subject is one which is attracting increased attention from the general public, and this booklet will no doubt be found useful by a large class of readers. It is a pleasure to be able to add that the information contained in it is equally trustworthy within the scope contemplated, and entertaining, because well arranged and clearly explained.

The work would be still more attractive, and its sphere of usefulness enlarged, if in another edition there were to be added to it two or three sketch maps and an illustration of a drilling plant. E. R. B.

THE AIM OF BIOLOGICAL TEACHING.

Biological Lectures Delivered at the Marine Biological Laboratory at Wood's Holl, in the Summer Session of 1895. Pp. 188. (Boston, U.S.A., and London: Ginn and Co., 1896.)

"I TRUST that you all, when you leave the laboratory, will carry with you a deeper and loftier enthusiasm for original research, which is at once the chief duty and the chief privilege of the biologist." Thus Prof. Minot concludes the discourse which he has contributed to this volume; and the sentence not only serves to illustrate the object of the lectures themselves, but at the same time expresses the ideal of that movement in biological teaching of which the lectures are a sign. It is to the credit of American teachers of natural science, and more especially of the teachers of biology, that they, more faithfully and successfully than their fellow-workers in this country, have striven to keep in view the true end and aim of all scientific teaching—a training in that method, whose ultimate goal is the increase of knowledge by means of scientific research.

The lectures now brought together in volume form were delivered, as the title states, at the Marine Biological Laboratory of Wood's Holl, in the summer session of 1895. At the laboratory there are assembled during the summer months a considerable number of naturalists engaged in biological research, together with a large body of university students, who have not yet completed their biological course, and the excellent practice has been instituted of inviting the investigators to deliver lectures upon their work for the benefit both of their colleagues and of the students.

To students who have been taught to regard scientific research as the end towards which all their studies are directed, nothing could be more stimulating, especially at a time when they are brought into such intimate contact with nature, as a residence at a marine laboratory affords, than lectures such as these, delivered by men who are themselves actually working at the subjects about which they speak. Yet we cannot refrain from remarking, what no one who has been brought into contact with English students with the dead hand of the examination hanging over them will deny, that for the latter such discourses would possess but little interest.

Our students, indeed, would seem to have no time to be interested; all they demand is something that will "pay," when the examiners are met. And the result is, as might be expected, that when the goal at which they have aimed is reached, with memories ruined and enthusiasm killed, they are helpless in the presence of the simplest scientific problem, and have yet to learn the very elements of the methods of attack. What they have been taught is not how to gain knowledge, but how to undergo examination.

Turning to the lectures themselves, and regarding them from the point of view for which they were designed, namely to awaken enthusiasm for the scientific method and to stimulate research, it must be admitted that they have a somewhat unequal value. Perhaps the most successful are those—such as that by Dr. Locy, on "The Primary Segmentation of the Vertebrate Head"—which are simple, straightforward statements of the researches upon which their authors are themselves engaged, and in which they are, therefore, themselves most keenly interested. And without expressing an opinion on the morphological theories which the author advances, we would single out this lecture by Dr. Locy, as being likely for another reason to be specially instructive to the student who is feeling his way to investigations of his own. No idea is more frequently met with amongst those who have just completed their academic training, than that our knowledge of common things—of things which are easily procurable and, as it were, ready to hand—is complete, or, at any rate, as complete as it can be made with the methods at present available; and as a consequence of this idea it is presumed that only by seeking for strange objects in strange places, or by the employment of some new and complicated method of research, is there any prospect of adding to the knowledge which already exists. Now, as Prof. Kingsley points out in his lecture on the subject in this volume, the question of the segmentation of the vertebrate head has occupied the attention of leading anatomists since the beginning of the present century, and perhaps no problem could be mentioned which has been more thoroughly investigated and discussed without a satisfactory conclusion being arrived at. On the other hand, no vertebrate embryo—not even that of the chick—has been more studied than the Elasmobranch embryo. Notwithstanding these two considerations, we here have Dr. Locy bringing forward a theory of the segmentation of the head, based very largely on a minute study of many stages of early embryos of Acanthias, *chiefly in surface views*. We could almost hope that Dr. Locy's theories may prove to be correct, for the sake of the valuable lesson which his success would teach.

In "Bibliography: a Study of Resources," Prof. Minot treats of a real difficulty which invariably confronts the young investigator at the outset of his work, and about which he is accustomed to receive little advice or help. The various methods are explained by which, amongst the vast mass of biological writings, the literature dealing with any particular subject may be most readily and completely discovered, and many practical hints on bibliography are given, which should prove exceedingly helpful to those for whom they have been brought together.

Prof. W. B. Scott's remarks on "Palæontology as a Morphological Discipline" contain many suggestive ideas, and Prof. Osborne gives some interesting "Reminiscences of Huxley." In reading these we cannot but call to mind how large a share Huxley took in establishing that system of biological teaching which, as at present carried out in this country, seems to call for serious condemnation; again an illustration of how a system, in its origin the embodiment of the thought of a master mind, may, in the hands of those that follow, become the mere corpse of an idea, better put from sight.

The least successful portions of the volume are the two lectures by Dr. Dolbear, entitled "Explanations, or How Phenomena are Interpreted," and "Known Relations between Mind and Matter." These are of a more or less metaphysical nature, and deal with some of the fundamental problems connected with the human mind and human knowledge. In treating such problems, especially before an assembly of students, the primary conditions of success must be that the propositions brought forward are stated in clear and definite language, without confusion of terms, and that there is not the slightest suspicion of any confusion of thought. That the lecturer cannot be congratulated upon having accomplished this, the following quotation is sufficient to show:—

"The spectroscope, an instrument for determining whether matter is solid or gaseous, when turned towards the sky showed that there were vast numbers of gaseous masses there and in many degrees of condensation. This discovery was held to corroborate the idea of Kant and Laplace, so that to-day there is no astronomer who does not hold the view that the Solar system as we see it to-day is a growth, that it was not made as it is, and that gravity with the simple laws of motion are sufficient in themselves to organise the Solar system as we find it, and an explanation of it is an exposition of how these factors brought it about."

We must be pardoned for expressing a doubt as to whether the students derived much benefit from these remarks.

Looking, however, at the lectures contained in this volume, as a whole, they must be regarded as possessing a very considerable value, not chiefly for what they themselves contain, but more especially as representing a movement towards a truer method of biological teaching, which cannot be too highly commended.

A STUDY IN SYMBOLISM.

The Buddhist Praying-wheel: a Collection of Material bearing upon the Symbolism of the Wheel and Circular Movements in Custom and Religious Ritual. By William Simpson. Pp. viii + 303. (London: Macmillan and Co., 1896.)

MANY people have seen a Buddhist praying-wheel, a small cylinder filled with written or printed prayers, and either surrounded by an outer case and turned by a twirl of a spindle, or else swinging round a spindle held in the hand. But besides these hand praying-machines, which so often find their way to Europe as curiosities, there are larger forms of the same instrument of devotion in the temples and villages of Thibet.

Huge cylinders inside the temples, turned by the priests, or rows of barrel-like cylinders along their outer walls, turned by a push of the hand of people passing in the street, or cylinders turned by water or wind, are common objects, and have never failed to attract the attention of travellers in that country. Such a traveller was Mr. William Simpson, who spent the hot seasons of 1860 and 1861 in the Himalayas, and in both years passed over the boundary into Thibet. He made sketches of the praying-wheels he came across, visited the temples, and watched the priests at their devotions endlessly turning the huge cylinders; he also bought one of the small hand-cylinders, and learned the proper method of using it. On his return to this country he collected what information he could, and, although in 1867 he wrote a magazine article on praying-wheels, his interest in the subject did not cease, for he continued his reading, the results of which are embodied in the book before us.

As its title suggests, Mr. Simpson has not confined himself to the Buddhist praying-wheel, but has extended his range of study to include the symbolism of the wheel in general which occurs in varied forms in different systems of religion, and has also touched on the circular movements and dances to be met with in the customs and ritual of many races. A glance at his index to book-references will show that Mr. Simpson has consulted a large number of very various works, from which he quotes passages which seem to bear on the wheel as a symbol, or on circular movements, and we gather that the principal contention or thesis that he seeks to establish is that the Buddhist praying-wheel, along with all forms of the wheel in symbolic art, has a solar origin, and that circular movements and dances which turn from right to left, are to be interpreted as symbolical of the apparent motion of the sun.

It has long been recognised that with primitive races sun-worship is a most important factor in ritual and belief; but that all symbolic wheels and circular dances can be referred to a solar origin in the wholesale manner our author appears to suggest, is a theory that most students of mythology will regard with some suspicion. Perhaps one of the most fundamental axioms of the modern science of folk-lore is contained in the strict line of distinction it draws between the beliefs of primitive and undeveloped races, and those of nations that for many centuries have enjoyed a highly-developed civilisation with an organised priesthood, and have been subjected to the various influences exerted by their own literature and the literatures of other nations with whom they may have come in contact. It has been abundantly proved that in two or three generations the influence of literature on a nation can work a complete revolution in its beliefs and superstitions; so that in tracing the origin and development of its rites and symbols, a completely different method of investigation and standard of judgment must be adopted to those employed in the case of less developed and more primitive races. The weakness of Mr. Simpson's theory, therefore, appears to us to lie in the fact that he does not lay sufficient emphasis on this fundamental principle. He has, in fact, approached his subject rather from the outside, to some extent neglecting—in the case of ancient and highly-cultured races—the infinite number of influences that have been at work to mould the form their beliefs subsequently assumed. It must be added, however, in fairness to the author, that he himself does not regard his theory as more than a tentative suggestion, and that he considers his book rather in the light of a collection of material: and as such it will, no doubt, be of considerable service to those who are interested in the subject. In conclusion, a word of praise should be given to the excellent illustrations scattered through the book, many of which have been reproduced from the author's own drawings.

OUR BOOK SHELF.

Physiography for Beginners. By A. T. Simmons, B.Sc., A.R.C.S. Pp. viii + 344. (London: Macmillan and Co., 1896.)

As an introductory science it is, perhaps, but natural that the scope of physiography should be somewhat nebulous and liable to occasional modifications; but after its long existence as a separate subject for the examinations of the Department of Science and Art, one would have expected it to have assumed fairly-defined boundaries. Nevertheless, although important alterations in the syllabus were made only a year ago, still more sweeping changes have been introduced during the present year. We learn from the official statement, that the syllabus "has now been so framed that it is, particularly in the elementary stage, a real introduction to the various branches of physical science. . . . One object of this revision has been to adapt it for pupil teachers who may be called upon to give object-lessons in their future career."

To meet the demand which has doubtless been created by the recent changes, is the object of the book under notice. It may be stated at once that the book covers the syllabus in the most complete and satisfactory manner, and we have no hesitation in saying that teachers will find it to adequately meet their requirements as a class-book. The descriptions are clear and not too long, and great pains have evidently been taken to ensure accuracy in every section. One of the best features is the great prominence given, for the first time we believe, to experimental illustrations of the subject, all those suggested in the syllabus having been incorporated, and others added to make a total of 216, all of which require but simple appliances. These, however, will absorb a certain amount of time; and, to economise a little, there is a summary at the end of each chapter which may well take the place of the notes which are frequently dictated to classes. Sets of questions to test the progress of the students are also included. The book is very generously illustrated, and although some of the figures are not new, they all admirably serve their immediate purposes. A complete list of the apparatus and materials required for carrying out the experimental work would form a very useful appendix to the book.

The Metric System of Weights and Measures compared with the Imperial System. By Prof. W. H. Wagstaff, M.A. Pp. vi + 121. (London: Whittaker and Co., 1896.)

ANYTHING that educates the public in the advantages of the metric system, and exhibits the cumbrous nature of the "weights and measures," preserved by British insularity to the detriment of British commerce, claims the commendation of men of science. For this reason we think Prof. Wagstaff has acted wisely in reprinting the four lectures on the metric system delivered at Gresham College a year ago. The resulting little volume contains a good general account of the metric system, and one which will excite interest in the subject. The best way to the introduction of the system is to instruct people in it; for as soon as a wide knowledge of metric

measures is obtained, the British system will drop out of existence as a natural consequence of the elimination of the unfit. Prof. Wagstaff not only describes clearly the metric measures, but he also brings together a number of facts and expressions of opinion for and against their introduction into the British Isles.

The Aurora Borealis. By Alfred Angot. Pp. xii + 264. (London: Kegan Paul, Trench, Trübner, and Co., Ltd., 1896.)

THIS is a translation of a book—"Les Aurores Polaires"—reviewed in this column in March 1895 (vol. li. p. 484). It is the eighty-first volume of the International Scientific Series, in the list of which it is correctly entitled "The Polar Aurora," instead of "The Aurora Borealis." Only upon the title-page and cover does the latter designation appear, each of the pages with even numbers bearing the former title. This inconsistency will probably lead to some confusion.

A comparison of the present volume with the original edition shows that the translation has been well done. We have, as the result, an interesting and lucid account of the present state of knowledge of the aurora in all its aspects, illustrated by pictures of the typical forms assumed. In an appendix, a list is given of the auroræ seen in Europe below latitude 55° from 1700 to 1890.

An index would be a valuable addition to the book.

Ros Rosarum: Dew of the Ever-living Rose. Pp. xxix + 292. (London: Elliot Stock, 1896.)

A SECOND edition has been issued of this delightful little volume. It contains extracts from works of poets whose songs have come down to us from all ages. In the interesting introduction the author states that many of the translations are due to the kindness of Lord Tennyson, Lord Lytton, Mr. J. A. Symonds, and many friends. Much information is also given concerning the history of the rose, and it is shown how highly this flower has been regarded at various times and in various countries. In both Athens and Rome it was recognised as the queen of flowers; there seems, indeed, to have been scarcely a time when it was not valued and appreciated. The book will be found very interesting; the quotations have been carefully collected and placed, as far as possible, in chronological order. It may also be added that one quotation from Lord Tennyson is not to be found in his collected works, a fact which adds interest to the little volume.

Knowledge. Vol. xix. January to December 1896. Pp. 288. (London: *Knowledge* Office.)

WE offer our congratulations to the editor of *Knowledge* upon the completion of this very attractive volume. The illustrations—many of them full-page collotypes—are most instructive pictures, and the figures in the text are just as good. The remarkably fine reproductions of astronomical photographs are particularly interesting. A series of twelve well-illustrated articles by Mr. Vaughan Cornish, under the comprehensive title of "Waves," also calls for special mention. It is not possible to keep up with the march of science in a monthly periodical; but *Knowledge* gives a good general idea of progress, and the present volume is full of interesting articles on comparatively recent work, illustrated by some of the best pictures it is possible to obtain.

Hygiene Diagrammettes. By W. H. Knight. (London: Chapman and Hall, 1896.)

THIS is a collection of twenty-four photo-zincograph reductions from large diagrams designed for teaching hygiene. Upon the page facing each of the illustrations are given brief descriptions of the separate drawings and tables. These notes, together with the instructive diagrams, should be very serviceable to teachers and students. It is a pity that the inscriptions attached to some of the illustrations are illegible, owing to the reduction of the originals having been carried too far.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Leonids of November 15, a.m., 1896.

THE display of Leonids on the morning of the 15th ult. was observed here under very favourable conditions of the sky for noting the progress of the shower in numbers and in brightness, and in the position and distinctness of the meteors' radiant-point or centre of divergence. As observations of this kind collected in the present early stages of the shower's gradual increase to greatest brilliancy seem likely to be very useful to improve our knowledge of the past history and mode of advent of this meteor-stream into the solar system, I send the following leading particulars of the shower as it was here observed.

The sky was cloudless during my watch from midnight until dawn appeared rapidly at six o'clock on Sunday morning, the 15th, excepting only in the hour from 4½ to 5½ a.m., when clouds spreading slowly hid nearly all the sky in the latter half of the hour, but dispersed quickly then in time for a perfectly clear half-hour from 5½ a.m. till daybreak. At this latter time the radiant in Leo, then preceding the mean sun as it did, about six hours in R.A., had reached its highest southern altitude of a little over 60°, or nearly that of the sun at midday in midsummer, while in the hour from midnight to 1 a.m. it was, like the sun in June-July at 6–7 in the morning, 20° to 30° above the E. by N. horizon, having risen above the horizon in that quarter a few minutes after ten o'clock. The moon, however, a little past her first quarter, shone strongly still in the west, hiding 5th magnitude stars till one o'clock, and only set, leaving the sky quite clear, at about 1.45 a.m. It may be owing to the obstacles of clouds in one, and of moonlight in another hour of the watch, that only one Leonid was recorded in each of the two hours from 4½ to 5½, and from 12 to 1 o'clock; but observations made elsewhere under better sky conditions, by Mr. W. H. Milligan in Belfast, and by Mr. H. Corder at Bridgwater,[1] show that there were really lulls in the shower's intensity before 2, and towards 4 o'clock, though it regained its brightness in the later hour from 5 to 6 o'clock; and neither the comparatively low altitude of the radiant-point, nor the moderate strength of moonlight till 2 o'clock seem sufficient to account satisfactorily, considering the brightness of most of the meteors which showed themselves very little later, for the marked scarcity of Leonids noted in the first two hours of the watch. The following numbers of Leonids and of sporadic or non-Leonid meteors were recorded (and most of their apparent paths were mapped) in the successive hours (or half-hours) ending at

Numbers of Sporadic Meteors	—	—	—	—	1	2	9; ,, 12

The second table shows how much the Leonids surpassed in brightness, as they also did in numbers, the ordinary appearances of shooting stars on a November night. The brightness of the display, and its rather sudden commencement, apparently at about 2 o'clock on the morning of the 15th inst., seem to point to that morning as having been at least a very conspicuous date of its return this year, although eager expectation of a shower on the morning of Saturday, November 14, was awakened in the

[1] *English Mechanic*, November 27, 1896:—"From 12½ to 2" (? Irish time, = 1–2½ English time) a.m., Mr. W. H. Milligan noted "9 Leonids; hourly number about 6." This was a rather low rate of appearance in that period. Mr. Corder began watch at 2 o'clock, and saw eight Leonids and two sporadic meteors in the first half-hour, "after which the numbers fell off; but when the radiant had risen higher, about 5 to 6 o'clock, 16 meteors were seen in an hour, nearly all Leonids." Descriptions of the shower's appearance on the preceding morning (of November 14), by Mr. Corder and Mr. E. R. Blakeley, in the same issue of the *English Mechanic*, and descriptions of the apparent paths of several bright Leonids seen in a clear hour at daybreak on November 15, by Mr. W. E. Besley, at Walthamstow, in the next preceding number of the same journal (November 20), are extremely interesting in this connection, and will presently be again referred to.

preceding days by ably written articles on the phenomenon in the leading daily journals, which could not be fulfilled and realised in England from the unfavourable state of the atmosphere for observations.

The earth should indeed have crossed the main meteor-stream of the two great showers of 1866 and 1867, supposing the node of the meteor-current's orbit to have been advancing at its accustomed pace on the ecliptic in the intervening years, at about daybreak, or between 3 and 9 o'clock a.m. on Saturday morning, the 14th, as predicted; but certain attendant meteor-clouds or clusters also exist, accompanying the main stream, and on 1865, November 13 (a.m.), a grand display of the Leonids was widely observed in Europe and America from midnight until daybreak, which, it was shown by Mr. B. V. Marsh [1] of Philadelphia, U.S.A., constituted a branch-stream twelve or fifteen hours earlier in the times of its maximum recurrences than the principal meteor-stream of the two great November-exhibitions of the next two years. And again, near Pekin in China, on November 15 (a.m.), 1867, and in America on November 14 (a.m.), 1868 (agreeing also with showers observed in England on November 14 (a.m.), 1868, and November 15 (a.m.), 1871 [2]) bright showers of Leonids scarcely inferior to the main stream's apparitions were witnessed, which, as was pointed out at the same time by Mr. Marsh, belonged to a branch-stream following the main stream, instead of preceding it, by about the same time of between twelve and fifteen hours as the other one, in its appearances. The Leonids of the 15th ult. appear thus to have appertained to this following branch-stream which the earth was probably passing through with sensible sparse gaps and condensations, for about 14 hours (according to its formerly observed durations) between dusk and daybreak on the night of the 14th–15th ult.; and if the two following and preceding side-streams are equally long, evenly extended belts with the main stream of meteoric matter, it may perhaps be expected that on the mornings of November 14 and 15 next year, the earth will come to be immersed in the preceding and following meteor-belts, respectively, while the main current encountered like the fellow-streams, six hours later than their predicted times this year will be traversed in the daytime of November 14, 1897, producing a principal meteor-shower then which in the full daylight will not be visible in England. In the years 1899 and 1900, on the other hand (the latter year a non-leap year), it seems probable that the brief but imposing scene of the earth's passage through the main stream, if no disturbances in its path since 1866-7 have warped the current out of its expected course, will occur more opportunely and more favourably for English watchers about at midnight and at 6 o'clock a.m. respectively, and one or both of them perhaps in pretty full completeness, on the mornings of November 15.

The general colour of the heads and streaks of the Leonids seen on the 15th ult. was dull yellowish white, or yellow, but some of the largest had bright white nuclei with white streaks. The head of one very fine one only, at 5.58, was slightly greenish, when brightest; but the long and broad dense streak which it left visible for 6 seconds, was of the same golden yellow colour as that which prevailed in the fainter streaks of ordinary durations (2–4 secs.), and of ordinary lengths (10°–20°), and which was now and then seen most distinct and vivid in the spindle-shaped foreshortened streaks left near the radiant point. This green and yellow-tinted meteor, brighter than Jupiter, and the last which I observed, shot through 40°, overhead across the dawn-lit sky, from the direction of *κ Leonis* so exactly to *β Aurigæ*, and directed there towards *Capella*, that that bright star-pair, prolonging the line of the streak's golden wand, as it appeared, which just reached the former star, looked with the streak like a grand jewelled sceptre in the sky, whose long staff only slowly faded.[3]

[1] British Association Reports, 1869, pp. 302–3.
[2] *Ibid.*, 1872, pp. 96–7. See also 1866, pp. 64–5 and 137.
[3] Had I provided myself with a hand-spectroscope for this occasion, this meteor's streak and a few of the most enduring ones left by the brightest meteors of the shower, would doubtless have presented very interesting features for spectroscopic study. By comparison with the sky-positions recorded of this meteor's apparent path at Walthamstow by Mr. Besley, a real path of the meteor is obtained by the base line of 28 miles W.S.W.–E.N.E. between the stations, from 90 miles over a point on the border of Sussex and Hampshire, halfway from Midford to Alton, to 27 miles over a point 5 miles east from Didcot, directed from a radiant point at 150° + 22°, then 60° above the S. by E. horizon; the length of the sloping path being 74 miles, which the meteor described, as was noted here, in 1¼ second. The beginning and end heights, and the speed of flight thus indicated by the calculation of nearly 50 miles per second, not surpassing much the real meteor-speed—43 miles per second—of the Leonids, lend much probability of correctness to the view adopted here, that though differing in the apparent magnitudes, and somewhat in the estimates, as described, of the path's apparent lengths at the beginning and end points, the two accounts at Walthamstow and Slough really referred both to the same bright long-pathed shooting-star seen to begin its course at both the stations in remarkably close proximity to a radiant-point almost identical in position with the principal one on that night in Leo. Seven meteor paths of Leonids were mapped in the hour from 5.38 to 6.42 a.m. on November 15, by Mr. Besley, of 1st–3rd magnitudes, and the last of them in strong-growing daylight, as bright as Jupiter. This bright white one, and three others, all beginning in and near Leo's sickle, diverged almost accurately from a common point at 149° + 22°, the remaining three only deviating, in respect to radiation, from 4° to 8° from that position.

Fine meteors leaving streaks along their whole path-lengths for four or five seconds appeared at—

Seen also apparently, at Walthamstow, by Mr. W. E. Besley, with the following description, and positions :—

5.59	2	141½ + 23	95 + 22	43	— (The *English Mechanic*, November 20, 1896.)

The meteors nearly all moved very swiftly, and described their paths, in general, at rates of about 10°–15° in half a second.

Much careful selection was needed from the mapped paths of the Leonids to obtain a satisfactory position of the radiant-point, as quite a volley of fine long-pathed streak-leaving meteors from a radiant, apparently in *Crater* or *Hydra*, far south of *Leo*, streamed in direction across *Leo* and *Cancer*, surpassing the Leonids in speed, brightness of the heads and streaks, and lengths of path, and frequently confusing themselves with the cometary shower as if they were exceedingly erratic members of it. One very resplendent one, whiter and brighter than Jupiter, set out, at 4.14 a.m., exactly from Jupiter in the middle part of *Leo*, and shot swiftly up across *θ*, *δ Leonis*, 35° to near the hindermost foot of *Ursa Major*, leaving a dense white streak 5′ broad for about six seconds all the way—a path which it would be difficult to reconcile with a radiant point near *gamma Leonis*, although the meteor in all respects, except in its globular white head, exactly resembled a Leonid. A position is given for December in Prof. Heis' and Dr. Neumayer's "List of Southern Radiants," of 1867,[1] at 148°, − 34°, which although much further south than one near *λ Hydræ* at about 150°, − 12°, which seemed to be active on the 15th ult., yet shows that there are showers with southern declinations at this time of the year near the meridian of the shower from *Leo*, almost as oppositely directed (and consequently as swift) in their motions as the Leonids are, to the motion of the earth. The meteors of the 15th ult. and of a few neighbouring nights, also showed signs of radiation from near *δ*, or *α* and *κ Cancri*, at about 137°, + 17°; and on a chart of meteor-paths recorded last year on the mornings of November 13–15, I find four long-pathed tracks traced back to a common radiant-point at 132°, + 17°, near *δ Cancri*, which they fitted well, and which perhaps confirms this place.

Omitting then as doubtful Leonids for this reason (or else for their distances from the chief focus of the radiation), out of the thirty real or possible Leonids mapped, all but those whose courses' prolongations backwards would cross the small area of the sky formed by completing the circle half traced by stars in *Leo's* sickle, the twenty-two paths remaining, all diverged from a circular tract 10° in diameter, having a point at 148°, + 23°, near the small star *x Leonis*, at its centre. But a circle only 6° in diameter, round a centre at 149° + 24°, also includes nineteen of these tracks very evenly distributed, if three at the south-west border of the larger circle are omitted; and accord-

[1] British Association Reports, 1868, pp. 405–6.

ingly this latter point, still very near to *x Leonis* in the middle of the sickle, was a very well defined and exactly marked centre of the shower's radiation, since nineteen out of thirty, or 63 per cent. of all the tracks of possible Leonids recorded, proceeded from within 3° or 3½° from it, outwards towards all directions.

The chief apparent wandering from this centre shown by the eleven erratic-flighted Leonids was south-westwards, towards *α, κ Cancri*, where seven of those outlying tracks (including the three wide-circle-grazing path-lines) are loosely collected; but of these seven, some may have belonged, as was surmised above, to contemporaneous sparse showers at about 135°, + 17°, and 150°, − 12°; and as the four paths which strayed north-eastwards from the sickle, though forming a fan-like group roughly focused at about 155°, + 35°, near *f, g Leonis Minoris*, were no doubt Leonid stragglers, shooting in proper numbers for their own half of a field supposed to be about evenly strewn with them, from no really existing radiant centre there, there would thus seem to have been among the strayed Leonids themselves no tendency that could be noticed to move in side-flows and tangent-streams presenting laterally drawn-out and branching radiations strong or distinct enough to be discernible. No such lateral dispersions or divisions, therefore, seemed, from all the tracks' projections, to have affected the shower's radiation with any perceptible apparent changes from the very exactly defined centre, with even, and not very great dispersion round it, which has been usually observed as a strikingly conspicuous feature of this star shower's radiation at its principal returns.

Positions of this after-shower's radiant-point, obtained formerly and in the present year, are not in very perfect, although in fair general accordance; as even in its bright display of November 14 a.m., 1868,[1] places were assigned to it, at Rome, "at the centre of the five stars of Leo's sickle" (149½°, + 22½°) at Moncalieri, Piedmont, "exactly between *γ* and *δ, ζ Leonis*" (153°, + 22°), and at Madrid, "close to *η Leonis*" (150°, + 17°; mean of these places, 151°, + 20½°). In NATURE, November 30, 1871, a description of the shower's appearance in England on the morning of November 15, 1871, assigns the radiant-point's position from twenty-six Leonid paths as "not very well defined, but approximately close to *ζ Leonis*" (152°, + 24°). On the morning of November 15 in the present year, Mr. Corder obtained a position of 150°, + 24°, from forty-three Leonids; and four of the seven paths mapped at Walthamstow at daybreak on that morning by Mr. Besley (see note on p. 174) diverged accurately from 149°, + 22°—all slightly onward in R.A. from the principal radiant-point in Leo at 148°, + 23°; but the positions are too slenderly consistent to make this small difference appear to be of very much importance.

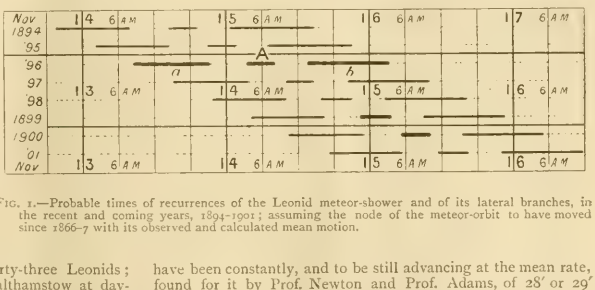

FIG. 1.—Probable times of recurrences of the Leonid meteor-shower and of its lateral branches, in the recent and coming years, 1894–1901; assuming the node of the meteor-orbit to have moved since 1866–7 with its observed and calculated mean motion.

In a watch for the Leonids, from 4 to 6 a.m. on the 15th ult. at Bristol, Mr. Denning mapped the apparent paths of ten Leonids and five sporadic meteors. Three of the Leonids (one of them a foreshortened flash as bright as Jupiter) diverged accurately from 150°, + 23°, the other seven (also including one as bright as Jupiter) being directed eastwards from the lower part of *Leo's* sickle-circle. Of the three true-pathed Leonids, a small, very foreshortened one, of 3rd mag., leaving a streak, which fell at 5.45 a.m., about 2° from *η* down the sickle-handle, was also seen and mapped at Slough, at 5.44½, of 2nd mag., leaving a streak for two seconds, but shooting through 12° in half a second to near *α Orionis* from the stars in the head of *Monoceros*, this path among the stars being from 50° to 60° removed by parallax (owing to the long base line of 84 miles, nearly due east and west, between Slough and Bristol) from the short course in *Leo* which it seemed to have from Mr. Denning's place of observation. The meteor's real path was found to be from the mean radiant-point of the shower at 150°, + 23° (then about 60° high above the S. by E. horizon), shooting steeply down through 24 miles, from 70 miles over a point 8 miles south, to 50 miles above a point 7 miles W.N.W. from Blandford, in Dorsetshire, the earth-point of this course being near enough to Bristol (about 20 miles south) to give a nearly end-on view there of the swift flight, subtending only 2°, while at Slough, where the flight was seen breadthwise, though more distant there than from Bristol, it subtended an arc in the sky of fully 12°. The computed speed of flight, 48 miles per second, although certainly terrific, does not exceed the known meteor speed of the Leonids, 43 miles per second, very greatly. One of the sporadic meteor-paths observed by Mr. Denning was directed from the vicinity of λ *Hydræ*, and the other four apparently from *Gemini* or *Taurus*, and from *Ursa Major*.

A fairly satisfactory comparison of this year's observations of the Leonids with the views obtained of them last year, although much frustrated by the cloudy weather which prevailed in England on those nights, in both years, when the earth's passage through the densest part of the meteor-system was expected, may be made rather scantily, but perhaps not insufficiently to show the increased intensity of the display this year in its gradual progress onwards towards its maximum The subjoined figure was prepared to assist the recognition of the separate streams of which returning signs have no doubt been visible in some of the present year's and of the last two years' watches. The relations of the leading and following side-showers, *a* and *b* in the figures, to the central one A, in duration and separation-distance, are supposed to be as shown by Mr. Marsh's similar projection in a figure[1] of the chief showers in 1865–68; for the leading showers, 12 hours, ending 6½ hours before, and for the following shower, 13½ hours, beginning 6 hours after the limits of the middle-shower's duration, whose entire range, in time, on the ecliptic also only reached 4½ hours for the two tracts together in which the earth there met with and passed through the middle stream in 1866–7.

The central stream's node on the ecliptic is also supposed to have been constantly, and to be still advancing at the mean rate, found for it by Prof. Newton and Prof. Adams, of 28′ or 29′ from a fixed, or of 57′ from the mean movable equinox, in each complete period (33¼ years) of the stream's revolutions; so that the earth returns to the meteor-node in 41½ minutes more than a true tropical year (amounting to 23 hours in a meteoric cycle), and in 30½ minutes more than a mean Julian year. The Leonid showers thus recur in successive years, as the figure shows, 6½ hours later in each year than in the previous year; but the 6 hours in this amount are corrected every fourth year, as in the present leap-year, by the supernumerary day, and only the half-hours accumulate in long times, and made the return of the after-stream *b* this year fall 14½ hours later, on November 14, than its appearance 28 years ago, in 1868[2] (for 13 or 14 hours, from near midnight in Europe until after daybreak in America) on the morning of the 14th then; and even shift its time of appearance into lasting on now, apparently through all the morning hours of November 15.

No striking exhibitions this year of either the middle or the preceding showers A and *a* appear to have been noted. At Slough, on the morning of November 13, only one true-pathed Leonid, with two from Cancer and Hydra, and three sporadic meteors were recorded in a sky half-clear, from 2 to 4 o'clock. In a watch of two or three hours on the same morning at Bridgwater, Mr. Corder noted twenty meteors, at a rate of eight per hour, and only five of these, or about two per hour, were Leonids. On the morning of the 14th, when the sky in England was generally overcast, similar numbers were observed; by Mr. Corder, in a sky often foggy, thirty-three meteors being seen at

[1] Reports of the British Association, 1869, pp. 293–4.

[1] Given in the discussion of those showers by Mr. B. V. Marsh, already cited above, in the Reports of the British Association, 1869.

[2] *Ibid*, 1869, pp. 289–94.

the rate of 8–13 per hour, of which only a small proportion still were Leonids, and by Mr. Blakeley at Dewsbury, who noted, from 12 to 4½ a.m., with two hours of quite clear sky at last, forty meteors, never appearing faster than fourteen per hour, among which were twelve Leonids with an hourly rate never exceeding six. Four or five of the Leonids were very bright, and their radiant-point was well defined at 150°, + 24°; but the whole display fell considerably short in brightness of that observed in 1895.[1]

Perhaps the three close-following meteor-showers may all have fallen a little later this year than the figure represents them; but the first few hours of watches on the mornings of November 13 and 14 should at least, as the diagram shows, have been (as they were) both slenderly productive times, while a bright meteor-shower should have prevailed (as it did, rather vividly) on the morning of November 15. On last year's November dates the case was different, a rather bright array of Leonids being seen on the morning of November 14, followed by a smaller one on November 15, while after the latter date a generally clouded state of the sky in England prevented further observations. At Bridgwater, on November 14, Mr. Corder mapped eleven Leonids between 2 and 4¼ a.m., and found their radiant point at 152°, + 23°. Five or six Leonids were recorded here between 12 and 3 a.m. on that morning, with a radiant-point at 151°, + 23°, to which were also traced the paths of two Leonids mapped between 1 and 2½ a.m. on the next morning of November 15, when the shower seemed to be passing off, and when clouds on that and in the next night's watch prevented a complete view of the shower from being obtained at Bridgwater, and generally in England. The spectacle was thus most prominently seen last year on the mornings of November 14 and 15, while it was this year most conspicuous on the morning of November 15; and this agrees with this trial-figure's indication that the early and middle branches of the shower should have occurred at favourable morning hours on November 14 and 15 last year for English observations; but at such late hours this year, as to be only weakly visible in a few slight foretokenings on November 13 and 14, compared with the full brightness of the after-shower brought into view on the morning of the 15th by the same advance in hour together of all the three members of the triple concourse. If the present positions and durations, then, of these component showers may be assumed to have been depicted in the figure with approximate correctness, a full view *of the end* and middle portions of *the first* shower beginning to appear in the next two years, 1897 and 1898 after midnight (a.m.) on November 14, will afford means of comparing in strength and brightness those phases of the leading shower with *the middle and early parts* respectively of the *after*-coursing one, then still well visible on November 15, to gauge their relative extents in length and width, and the relative looseness or compactness of their structures, which may perhaps not offer themselves again so favourably for some years.

It will also be very useful in coming years' watches for these detached clouds of fragments from the meteor-comet, to note exactly the hours of the watches kept, the states of sky and moonlight, with the numbers and brightnesses of the Leonids and sporadic meteors seen, to enable a true distinction to be drawn between bordering diffuseness of the streams, and really distinct branch-currents or offshoots from the meteor-cloud; for between 4 and 6 a.m. on November 17, and from 2 to 5 a.m. on November 18, last year, Mr. Corder found true-pathed Leonids almost as numerous (11 out of 22 meteors, and 8 out of 30 meteors) compared with the sporadic shooting-stars, as on November 14 (11 out of 26 meteors), from 2 to 4 a.m.; while on the previous morning of November 13, from 2 to 4½ a.m. only 3 or 4 Leonids were seen among 18 meteors; showing that both gaps and condensations reaching to considerable but as yet not fully determined distances from the main streams exist to either side of them, of which the extents and the changes, or the fixity of distribution would be very interesting particulars of their modes of assemblage to endeavour to trace out by observations.

On the morning of the 27th ult., in clear sky, between 1½ and 3 a.m., seven small meteors were recorded here, two of which, of 1st and 2nd mags., and orange colour, at 2, and 2.42 a.m., between *ι* and *o Honorum*, radiated with short slow courses from between *β* and *δ*, and from near *γ Andromedæ*, and were evidently fore-shortened Andromedes; but the first of them, at least, was quite as erratic from the true centre, near *γ Andromedæ* of the Bielan shower, as the tracks through *Cancer*, *Hydra*, and *Leo Minor* of the recent showers of Leonids have been from their native shower's true radiant-point. The horary scarcity of these small Andromedes on their annual date this year, showed that no brisk Biela meteor-shower was then in active progress. On the two evenings immediately preceding and following this short morning watch, the sky here was quite overcast. A. S. HERSCHEL.

Observatory House, Slough, December 9.

[1] The *English Mechanic*, November 27, 1896. At Funchal, in Madeira (1h. 8m. W. long. from Greenwich), Leonids were seen falling at the half-hourly rates of 6, 9, 6 in half the sky, from 4½ to 6 a.m. (about 5.40 to 7.10 a.m., Greenwich time), on November 14; the similar rates between 2 and 4½ a.m., in equally clear sky, having been only 3, 1, 1, 2 and 1 in half an hour.—Letter from Mr. W. Anderson, in the *English Mechanic*, December 11, 1896. *Note*, December 15.—A. S. H.

The Force of One Pound.

DR. LODGE has some right to complain of the friendly post-card. I wanted the *Poundal* difficulty to be threshed out in public, and we had just been writing to each other about it, but I quite forgot that my post-card might give him the wrong notion that my general remarks referred to him. Dr. Lodge knows that the real question before us concerns the Poundal; he knows that his advocacy of it has helped to maintain that unit in its academic position, and yet he now leaves its defence to others. He professes his love for all units, and attacks the poundalists and the poundists impartially, for suggesting adherence to any system in particular. This is better than his own maintenance of the Poundal, and I hope that it presages a complete change of front. His maxims are of the best: "Urge clearness of idea and accuracy of speech on all who deal with the junior student. These should not call different things by the same name . . ." But what if they continue to do so? He himself often uses *velocity* when he only means *speed*.

A pound of force, a pound of stuff, the inertia of a pound: here are three very different things all with the same name. When the chemist tells us that there is the same quantity of matter after as before chemical combination, what does he mean? He means that the *weight* of it is the same; the force of attraction by the earth. A certain amount of oxygen is equivalent in a certain property (its weight), to a quantity of hydrogen, and he says that he will call the quantities equal. Certain quite different amounts of them are *equivalent* in another property; he has exactly the same reason for calling these other amounts equal. A ton of iron is equivalent in a certain property to two ounces of gold. Why not call these amounts equal?

A pound of gold is no more the same as a pound of iron, because their weights and inertias are the same, than two chairs are the same as one table because they may be equal in value. I hope that Prof. Fitzgerald may be induced to say something on this head, the "huggermugger" of confounding quantity of matter with inertia; for I think with him that this is what produces far more confusion in the minds of students than the use of many different units for things of the same kind. The practical engineer has uncommon good sense, he hates the Poundal, and I think that Prof. Fitzgerald is right when he says that it is not merely because it is a new unit, but because it is founded on "huggermugger." Let Dr. Lodge read Mr. Jackson's letter which followed his own. He will see that Mr. Jackson cannot comprehend how anybody can avoid using the pound of stuff as a fundamental unit, and how it must be innate perversity which causes engineers to adopt as their unit of inertia (or mass, as they have unfortunately to call it), the inertia of a body to which the unit force gives unit acceleration. This is the fruit of the Poundal; no doubt its inventor thought of inertia. Mr. Jackson thinks of quantity of stuff, which is a conventional or metaphysical idea.

The standard units of time, of force, of inertia; we can only keep them in indirect ways. Assuming that waste is prevented and that the weight and inertia of a certain body measured under the same circumstances at the same place are always the same, any standard body with proper comparing instruments gives us our standards of force and inertia. The instrument for comparing forces is ready to hand, a good weighing balance. There is no instrument which can be relied upon for comparing inertias, so we fall back upon an indirect method, assuming that inertia at any place is proportional to weight. But it is to be noticed that all our practical acquaintance with inertia and with what we call quantity of matter is based upon our measurement of *weight*, of

force. A piece of metal is kept in London; it is defined as having there the weight of 1 pound, but only if weighed in a vacuum. Because it has this weight it is called 1 pound of stuff. Because it has this weight its inertia is said to be that possessed by a body whose weight is 1 pound. Now there are your standards in one piece of metal and in its environment, and in your instruments. You can keep the name 1 pound as the *weight* according to law, or you can call 1 pound the *inertia* of the body, but you cannot call it 1 pound of quantity of any material except of that particular kind of *Pt*. Which is more convenient? To call it the unit of a kind of *Pt* is too restrictive. To say that it has 1 pound of inertia is not more scientific than saying that its inertia is 1/32·19. As to convenience, note that we almost never need to speak of the *inertia* of a body except on our way to a dynamical calculation. The claim of *weight* of 1 pound as a unit of force is ever so much greater; for (1) there is the legal unit in existence. It might have been defined as the force required to elongate a certain spring, but this also would have been indirect. (2) All practical men use the unit already, and it is hopeless to try to alter their systems of working. All applied mechanics and engineering books written in the English language, from Rankine's superb treatises to the commonest pocket-book, use this unit; not one such book of repute can be mentioned in which the Poundal is used and in which this unit is not used; Joule used it, and many others of our best experimenters; even physicists never compare their forces in any other way than with the weights of bodies, and the pound is legally the English unit of weight. (3) The unit is so exceedingly easy to understand that years have now to be spent in driving it out of a pupil's mind; there is no part of our universe which we can reach where we might make experiments, where the unit is not easily derivable by a small and often negligible correction from the weight of a body whose weight in London is equal to that of the standard piece of platinum, and such bodies are to be found wherever men buy and sell by weight.

I think that Mr. Jackson is well answered in a quotation, slightly altered, from Dr. Lodge:—

"To identify quantity of stuff and inertia is barbarous, to denote their units by the same name is unwise."

By the bye, I should like Dr. Lodge to point out where I have lost sight of the dimensions of g and treated it as a mere equivalent for 32·18. One might say that it was stupid, or thoughtless, or academic, but I hardly think that Dr. Lodge is happy in his use of the term "illiterate." Anyhow, I did not do it. Engineers do not do things of that kind.

Mr. Cumming thinks that a system of theoretical dynamics can be built upon our basis; he does not seem to be aware that the system is already built; the ordinary dynamical expressions have no more to be altered when our units are employed than when the C.G.S. units are employed, and we do not need even to introduce Dr. Lodge's method of writing, which gives so much trouble in all but the very simplest algebraic expressions, but which certainly enables him to use any units whatever. I am afraid that it is known only to a few people as yet, but it is well worth knowing, being almost a necessity if one uses the Poundal or the Hogshead. It is simply this: every quantity goes about with a label as of a sandwich-board round its neck. Parenthetically I may say that Mr. Cumming is mistaken in thinking that engineers use the C.G.S. units in working with such fundamental equations as

$$V = \left(R + L\frac{d}{dt} + 1/K\int dt\right)C.$$

They use volts, amperes, ohms, secohms, farads, and seconds. Why else were the practical units invented? They were invented by practical engineers who at the same time invented the C.G.S. system, because they found that for the working of engineering problems, accurate answers and not merely academic logic was wanted. Unfortunately the academic 4π trouble was introduced, and till it is removed the practical man feels that life is a burden. These engineers were, as so many of our best engineers have been, trained at Cambridge, and this is one reason why I do not like to hear Dr. Lodge throw so much blame on Cambridge text-books. My opponents are not in agreement among themselves. I wish they were all as catholic in their sympathies as he. He wonders why people object, and who they are who object to the term *centrifugal force*. I think he must know many; anyhow there are certainly some, for they have told me so themselves during the last few weeks. And even he is now disposed to prohibit the use of a word, never used wrongly by engineers, because the present generation of academic persons have found out that their predecessors had very wrong notions.

I do not see why he should speak so disrespectfully about that most wonderful property of a body, its attraction by and for the earth, which I will call its *weight*. He calls it "a curious and ill-understood deportment," and his dislike for it is due to its having "laid such hold of the engineer's imagination that he has begun to think it the most fundamental property of matter." I am glad that he concedes the engineer an imagination in spite of his not understanding the so easily understood "etherial stress." For my part, I acknowledge great ignorance about it, and I think it the most fundamental property of matter.

His students are very happy; they know all about etherial stress; they know how to use all units, any units, to get along with no units, and, in fact, Dr. Lodge seems to think that what he himself knows, after all his years of study, must also be known to his students because he has told them. I may say that I also delight in using all sorts of units.

I perhaps go further than Dr. Lodge, for I regard algebra as the best of all mediums for translating phenomena into mental processes, and I should not object to the multiplication of a cows + b bridges with c cows + 5 tons of sugar, if I could see any use in giving a meaning to such things as cow × cow or cow^2 (curiously enough, Dr. Lodge would object to cow squared as a colloquial reading of cow × cow), or cow × bridge. But surely the student described by Dr. Lodge is a very exceptional philosopher, a boy of eighteen, with all Dr. Lodge's knowledge. Is he not assuming that because a student gets marks on an examination paper, he really knows his subject? How easy it is for a student to get full marks for "What is Ohm's law"? But how many years of his life must elapse before he really knows Ohm's law? Or "What are Newton's laws of motion"? How very easy, and yet how exceedingly difficult. Take force = mass × acceleration. A student thinks he understands perfectly what you tell him, and can work all sorts of exercises on this statement. But let the thing come before him in a new form, and where is his knowledge?

Dr. Lodge *thinks* in all his units, and in my opinion the students of whom he speaks cannot think in them. I want to put students in the way to the mental position which Dr. Lodge postulates as the best. I want them to get into a higher position still, that of the engineer who is able even to think of the same sorts of terms in one equation being in quite different units.

Dr. Lodge would dilate on the ignorance shown by this engineer. Mr. Barrie, in describing two boys in one of his books, says, "Shovel knew everything, but Tommy knew other things."

In my article I refer to the persistent scorn of the academic philosopher for the engineer and the harm that it has done. Surely Dr. Lodge might restrain it a little in a public discussion. All English-speaking engineers use the force of one pound as their unit, and Dr. Lodge sneers at it as the colloquial unit of the shire in which an engineer happens to live. The shire is a very extensive one. It needs a globe to show it all. He sneers at the Heaven-born engineer of whom I spoke, and of his wish to advance in his profession, and the mutilated fragment of science and pocket-book information which serves for commercial purposes. He seems to be very proud of his ignorance of these commercial purposes to which so many students of higher physics mean to devote themselves, and yet he is not backward in expressing his opinions concerning them. He says: "May I tell Prof. Perry what is at the root of the perennial debate between engineers and teachers of mechanics? It is the subject of *acceleration*. An engineer's bodies are nearly always either at rest or in uniform motion, their accelerative stages he is usually able to ignore." If anybody can speak on this subject, surely it is I. I was trained in the shops and at college as an engineer, and I have done a good deal of engineering work, and I teach mechanics. I beg to say that Dr. Lodge is quite wrong in this. When I wrote about professors and engineering students I did not once think of him I think now that he has written in haste, and that he cannot seriously put forward the view that the very most elementary idea of kinetics is unnecessary to the actual professional work of the engineer! Is it, then, of no use in any practical work of anybody? Has Dr. Lodge no students who think of the forces acting between the parts of reciprocating machinery, of the balancing of engines, of the action of governors, of the effects of centrifugal force? It

is a very grim joke, but we must bear with it and many others of the same kind, and in the meantime we do say that we agree with Dr. Lodge in his notion that our true and only natural foes are ignorance and prejudice. This ignorance of the needs of mere mechanical persons and prejudice against attempts to teach them, are fashionable now among scientific men. At the recent dinner of the Royal Society quite a genteel titter greeted a casual reference to technical education in one of the speeches.

I like algebra myself, but I do not think that it is the only possible conventional way of making an exact statement. However, taking Dr. Lodge's student with his "true from the bottom upwards and entirely true," mariner's formula to find a certain academic distance; is it quite certain that he will think of using it in a practical case? In my experience it is the very last thing that will enter his mind. I should not call him an ass, as Dr. Lodge does; he only follows Plato's maxim, not altogether neglected in English education, that philosophy ought to serve no useful purpose. The Wrangler's naïve faith, when he does condescend to a practical problem, is generally shocked in finding that such problems require the addition of a little common sense to the formula. Now I do not object to a man's finding out the usefulness of a rule (call it a mere numerical rule if you like, but it is evidently a very different thing), in actual practical examples before he understands how it is derived, for I am confident that he will then be easily induced to inquire how the rule is arrived at; he will go further and think of the evidence for the roundness of the earth, and indeed it may prove to be the starting-point in his scientific education. I grant you that he will not go far if his instructor makes him begin his studies with the six books of Euclid. Why does the mariner remain so ignorant of mathematics although he uses the results every day? Surely he wants to know the why? Yes, indeed he does, but you have taught him that he cannot know the why unless after years of quasi-philosophic worry.

When I spoke of the practical knowledge needed by the engineer, I meant to include such knowledge of physics as is possessed by Dr. Lodge himself; I mean no mere pocket-book knowledge. Before a student can get to this higher region he needs to be taught to think, and it is in our notions of this preliminary training that I differ from Dr. Lodge.

I do not care much what a man's system of teaching may be; if it is his own, however faddy, he will teach his students better than on a better system, not his own. But we must acknowledge that the average teacher needs a system to be given to him, and this ought to be the best system. Well, I think that the existing system is about the very worst possible. We compel a student to boggle at imaginary difficulties. We worry him for years over four books of Euclid; we have given up the fifth book, and even the supplement to the fifth, but we still worry him with the sixth, and then go on to geometrical conics. Now even the sixth book merely involves ideas which every boy takes in without much difficulty; it is so natural to think of using any unit of length, that Dr. Lodge forgets how the ideas of the sixth book are needed in his simple mariner's rule. But as soon as a student begins his work in physics, he is rushed over difficulties to which the difficulty of thinking about the mere ratio of lines is nothing. I do not say that he ought not to be suddenly surrounded with ideas of the sums and differences and ratios of all sorts of scalar and vector conventions for quantities, and told to sink or swim among them. I think this the very best thing for him; but what of your consistency in mind-training, of the philosophy of your methods? Dr. Lodge compels me to describe my non-academic way of teaching. I thought that everybody knew it, but evidently he does not.

I believe in using the experimental method from the beginning; of squares and ratios of sides of all sorts of right-angled triangles being figured out by the boy of eight years of age, to see how near he gets to tabulated sines and cosines. I believe in his measuring time and lines and forces with the watches and scales and balances which are in common use; in testing the rules of mensuration of areas and volumes, and the finding of weights of bodies by calculation; and it is only when a boy has a good quantitative knowledge from his own experience that I trouble him with the philosophy of mathematics and physics, and then I do it cautiously. I make beginners plot curves on squared paper—curves showing the rate of increase in the price of silk or cotton or the height of the barometer, or the National Debt or other things given in Whitaker's Almanac—in telling them about the slope of a curve and its analogy with velocity and acceleration and dy/dx and ds/dt and d^2s/dt^2. They "graph" all sorts of curves; they add and subtract vectors by actual drawing, and their lectures and laboratory work and graphical and numerical exercise work go on simultaneously.

Some of my academic friends not only refuse to let a student use a formula, but they refuse to let him use a table of logarithms until he can calculate logarithms. To be consistent they ought to refuse the use of a watch or of clothes until a student has shown aptitude in the watchmaking and tailoring trades. I let my students use any appliance whatsoever if I think that it will give them a better acquaintance with natural phenomena; anything that will cause them to think. As a student gets on I let him take all sorts of liberties in regard to units; he uses w/g for m; he speaks of centre of gravity instead of centre of mass or centre of area.

Also, I venture to tell Dr. Lodge that the very best of my students, who know something of Bessel functions and spherical harmonics and elementary St. Venant work on the torsion and bending of prisms, and something about generalised coordinates, are taught to have the very highest respect for the rule-of-thumb practical methods of calculation in use among engineers. They are taught that the engineer has to deal with things that are by no means so simple as the ordinary laboratory phenomena, and that rules arrived at through the trials and errors of generations of practical men are worthy of some respect.

Lastly, I may say that we are tired of the whole academic system which recognises no philosophy or literature or art which is not studied as a dull grind for examination purposes, and I am thankful to say that we have indeed "a sympathetic faith in a much larger training." JOHN PERRY.

December 17.

The Earthquake of December 17.

IT may interest your readers to know that the recent earthquake of December 17 was shown slightly on the declination curve, and more distinctly on the horizontal force curve, at Kew Observatory. The time of commencement was 5h. 35m. a.m. (± 1 minute) G.M.T. The disturbance on the horizontal force trace approximately equalled what would have been produced by a change of 0·00004 C.G.S. units in that force.

CHARLES CHREE.

Kew Observatory, Richmond, Surrey, December 19.

EARTHQUAKE shocks occurred in Worcester at 3.35 and at 5.31 a.m. on Thursday. The 3.35 shock was feeble, of short duration, and was noticed but by few persons. But the visitation of 5.31 exceeded in violence any previous instance of seismic energy here within the present century. There were in the 5.31 instance two shocks following each other with a bare interval. The shocks consisted of a series of rapid vibrations, too rapid to admit of count. These shocks were preceded by a roar as of thunder. Some describe the roar as that of the noise of a "rushing mighty wind." My house was shaken with appalling violence, displacing roof tiles, and forcing open a closed chamber door. To me the shocks seemed to proceed from north to south. The duration of the shocks lasted between four and five seconds. Some say the shocks lasted fifteen seconds; but if the earthquake had lasted so long, my house would have been down. As it was the house was rocked to its foundation, and the sensation was appalling. Persons whose bedrooms faced the north, saw a great light accompanying the earthquake. This peculiarity is by some attributed to lightning, by others to the effect of a large meteor. Mr. Russell Dirrell, of North Piddle, a place seven miles east of Worcester, saw at the time of the earthquake a great blaze of light low in the northern horizon, continuing for two or three seconds. He was unable to attribute the blaze to a lightning effect. At the homestead of Mr. Walters, of Hallow, three miles north of Worcester, the inmates were thrown out of bed, as was the case in several other instances in the same village. Here the shocks were most severely felt at places on the west of the Severn. In Worcester the shocks created general alarm. Bells were set ringing, shut doors forced open, windows rattled, heavy wardrobes displaced, earthenware scattered about, in some instances broken, but no one was injured. A strong fixed wash-hand basin in a lavatory was split to pieces. The church clock of All Saints, on the east of the Severn, was stopped at 5.15 a.m. As seems to be usual in such cases, poultry and pheasants flew down from their perches and showed signs of distress, birds flew aimlessly about and

clamoured. Graziers noticed that their milch cows were greatly trembling and seemed dazed, and horses ran about the pastures. During the shocks the river Severn here suddenly surged and angrily foamed up to the level of its banks, subsiding to its former level on the cessation of the 5.31 shocks. At Hallow, a labourer stooping to lace his boots was pitched headlong into the fire.

The season here has been marked throughout by exceptionally low readings of the barometer, such as 28, 50, 28, 70, and 29. The thermometer in my bedroom at 5.31 on the 17th was 38. The direction of the wind was northerly.

Worcester, December 19. J. LLOYD BOZWARD.

(1) THE only record that I have seen here, undisturbed as yet, of the measurable displacement of any object by the shock, is that of a large iron ornamental vase on pedestal, weighing at least 100 kilos., standing in the middle of a lawn on a stone foundation sunk in the ground. This has been moved sideways on its foundation through a space of 3 cm. I laid a long straight lath close to it in the approximate direction of displacement, and took compass readings near each end of the lath (to eliminate any deflexion due to the mass of iron). The mean of the readings gives magnetic N. 18° 30′ E., as the direction of displacement of the mass. The true direction may, however, have been rather nearer to magnetic N., for the pedestal is square and slightly sunk below the surface; and as the sides were forced obliquely against the turf, the motion may have been deflected from the line which would have been taken if there had been no resistance.

(2) One piece of evidence that the plane of the oscillation here was mainly, at any rate, horizontal, may be worth giving. I have a barograph (Richard Frères pattern) screwed firmly to a bracket attached to one of the internal walls of the house. The long recording arm of this is so sensitive to changes of vertical pressure, that the mere employment of a housemaid's brush near the instrument is enough to cause a vertical displacement of 1–2 mm. in the ink-trace; and, contrary to instincts of tidiness, I have had to give a caution against dusting operations in the neighbourhood, so many "dust-storms" have been graphically registered.

If, then, there was any vertical movement in the wall during the shock, there would undoubtedly be a straight vertical line on the ink-trace. If the movement was purely horizontal, the pen would simply be jerked away from the paper, and would fall back to its former position.

I examined the register shortly after the shock, and could find no trace whatever of any vertical irregularity in the barometric trace. The air-pressure, I may also mention, was remarkably uniform during many hours preceding and following the shock.

(3) Lastly I would note, as an evidence of weakness and probable strain in the strata of this district, the extensive line of fault (or rather two parallel adjacent faults) which runs nearly N.N.E. and S.S.W. through Newent, between the Malvern Range and Hereford, where the shock seems to have been most severe. On the west side of these faults, we have on the surface the Old Red Sandstone; on the east side, the Keuper Marls, the Old Red having been thrown down at least 4000 feet.

Gloucester, December 19. E. R. P.

THE EARTHQUAKE.

UNTIL last Thursday, the great Essex earthquake of 1884 held the premier place among British earthquakes of the last few centuries. So far as structural damage is concerned it is not yet displaced from that position, for, though in many places chimneys were thrown down by Thursday's disturbance (at Hereford at least one of the pinnacles of the Cathedral was damaged), yet there does not appear to have been that wholesale destruction which marked the Essex earthquake at Colchester and the surrounding villages. With regard to disturbed area, however, the inequality is reversed.[1] Though the recent shock occurred at a time (5.32 a.m.) when many observers were asleep, there can be little doubt that it was practically felt over the whole of England and Wales. At present we have only to exclude the terminal counties of Northumberland, Norfolk, Suffolk, Kent and Cornwall; and possibly these exceptions will disappear when fuller details are obtained. So far, no record has come from Ireland, but there can be little doubt that it must have been felt along the east coast, if not for some distance inland.

With regard to my own observations, I was roused at 5h. 32½m. from a dream of earthquakes, by a series of fairly strong regular vibrations of approximately equal intensity. Those I felt obviously belonged to the second half of the shock; they were eight in number, occupied exactly three seconds, and were of equal period, except that between the fourth and fifth the interval was half as long again as between the others. The motion was distinctly lateral, from a nearly westerly direction, the return movement being less perceptible than the forward, so that the shock appeared to consist of a series of firm powerful shoves. No sound was heard during these last three seconds, though I awoke with a feeling that the noise had just ceased; and this fact led me at once to assign a somewhat distant origin to the shock, possibly somewhere in Wales. As telegrams gradually arrived from various parts, it became evident that the epicentre must lie to the south-west, at some fifty miles from Birmingham.

The area within which buildings were damaged, includes Hereford, Ross, Worcester, Gloucester, Dursley, Cinderford and other places, and is not less than thirty miles in length. It would be premature to make any definite statement as to the exact position of the epicentre, or to suggest any fault with which the earthquake may be connected. But when these places are plotted on a map, one cannot but be struck by the fact that the district within which they lie agrees very closely with the epicentral areas of two previous earthquakes, those of October 6, 1863,[1] and October 30, 1868.[2] The former of these was a distinctly strong shock; and even now, in making earthquake inquiries in the district, I frequently receive references to it.

As I am collecting materials for a memoir on the earthquake of Thursday, I should be glad if I might take this opportunity of appealing to all readers of NATURE who can in any way help me, either by describing their own observations, or inducing others to do so. A brief list of questions having recently appeared in NATURE (vol. xlvi., p. 401), it is unnecessary to reprint them here.[3] They will also, I hope, be found in many local newspapers. If those who have the opportunity would examine the records of self-registering instruments, some useful information might be obtained with regard to time of occurrence at different places. I need hardly say how interesting it would be to have photographs of buildings which have been in any way damaged by the earthquake. I should also be very grateful for any notes, however scanty, on the earthquakes of 1863 and 1868; for, if the suggested connection between them and the recent shock should prove a true one, they will in all probability furnish important evidence as to the later stages in the growth of the originating fault. C. DAVISON.

373 Gillott Road, Birmingham, December 19.

P.S.—Since the above was written, I have received records from places in each of the counties mentioned above as apparently undisturbed, and from one place in Ireland (co. Wicklow). C. D.

December 22.

[1] The disturbed area of the Essex earthquake is estimated by Messrs. Meldola and White at about 50,000 square miles. This has been exceeded on two later occasions by the Pembroke earthquakes of August 18, 1892, and November 2, 1893, a paper on which will be read before the Geological Society on January 6 next.

NOTES.

THOSE who take a great interest in the welfare of our Colonies will be glad to hear that the Queen has been pleased to appoint General Sir Henry Wylie Norman (Chairman), Sir Edward Grey, Bart., and Sir David Barbour, to be Commissioners to inquire into the conditions and prospects of the West India Sugar-Growing Colonies; and Mr. Sydney Olivier to be their Secretary. Mr. Daniel Morris, Assistant Director of the Royal Gardens, Kew, will accompany the Commission as expert adviser in botanical and agricultural questions. The appointment of Mr. Daniel Morris as scientific adviser is a proof that Kew has been working for the last quarter of a century on the right lines, and that its policy is a sound one. Of all the Colonies in the West Indies, Jamaica is the only one in a fairly prosperous condition. This has been brought about mainly by the work of the Botanical Department, and the encouragement given by it to improve agricultural methods and introduce new industries. The Commission starts early in January, and will be away altogether about four months. It is regarded as one of the strongest that has ever been sent from this country.

AT the annual meeting of the Paris Academy of Sciences, on Monday, an Arago medal was awarded to Lord Kelvin in honour of the jubilee of his professorship in Glasgow University. M. Cornu (the President) is reported by the *Times* correspondent to have referred in glowing terms to the celebration at Glasgow. "Nothing," he said, "was more touching than the number and unanimity of the testimonies offered from all parts of the world to this descendant of a family of Irish farmers, who by his intellectual power has gained universal renown, and has earned from the suffrages of his admirers the highest scientific dignities, and from the Government of his country the highest social rank. Nothing is more consoling for the future than the spectacle of these honours rendered by delegates of all nations to great men of science like Lord Kelvin and Pasteur, who so worthily represent science in its loftiest and, at the same time, most beneficent aspect. Modern nations, though crushed by the yoke of material interest and by the barbarous law of blood and iron, know how on great occasions to raise their eyes towards the serene regions above animosities and covetousness, and to honour in unison the great men whose labours increase the common patrimony of intelligence and their country's prestige, as well as the welfare of mankind."

PROF. ARTHUR SCHUSTER announces to us the discovery of a somewhat important new law, connecting the wave-lengths of different lines of the same element. If the lines of an element be divided into series according to Kayser and Runge, the law may be enunciated as follows: "The difference between the frequency of the fundamental vibration and the frequency towards which the lines of the principal series converge, gives the convergence frequency of the two subordinate series." Prof. Schuster finds that the law holds in all the cases for which Kayser and Runge have established the existence of a principal and subordinate series, *i.e.* for the alkalis and the two constituents of cleveite gas.

SEVERAL communications on the recent earthquake will be found in other columns of this issue of NATURE. As observations of the times at which the disturbances were felt are of importance, we add that Mr. Alderman Andrews, of Coventry, informs us that he was awakened by a loud rumbling noise at 5h. 35½m. Mr. George J. Burch, of Oxford, did not note the exact time, but he carefully observed the phenomena. He says: "I was awakened by the hooter at 5.30, and had not gone to sleep again. About ten minutes later I was aroused by a movement of the door, as if some one was about to come in, but became instantly aware that the sounds proceeded from the whole of that side of the room. Immediately after, there was a heaving motion of the bed, as if powerful hands had gently raised the mattress slightly on that side, and let it drop. By this time I was sitting up, and distinctly felt the room rock two or three times like a small boat when a steam-launch has passed at some little distance. This was followed by a sudden strong lateral vibration lasting several seconds. There was a good deal of rumbling noise at this time, undoubtedly due, to a great extent, to the creaking of the house and rattling of the furniture, but whether entirely so or not, I am not able to say. Taking all things into consideration, I conclude that the line of the shock was north-east and south-west, and, judging from the sensation, it appeared to come from the north-east."

THE tercentenary of the birth of Descartes was celebrated at Tours, on Monday last, by the local Archæological Society.

M. LIARD, the Chief of the University Department of the French Ministry of Education, has been elected a member of the Academy of Moral Sciences, in succession to the late M. Jules Simon.

WE learn from the *British Medical Journal* that the Czar of Russia has conferred on M. Gérard, Director of the Paris Municipal Laboratory, the Cross of the Commander of the Order of St. Anne. The Cross of St. Stanislas has been conferred upon Dr. Bordas, sub-Director of the Laboratory, and Dr. Bertillon, Director of the Anthropometric service.

REFERRING to the decoration which Dr. Roux has just received from the Emperor of Germany, the Paris correspondent of the *Times* recalls the fact that "two years ago Pasteur was offered the highest German decoration which the Emperor could confer, but the great investigator refused the honour. The Emperor was apparently touched and certainly was not offended, for he has now decorated the famous Dr. Roux, the discoverer with Dr. Behring (who, moreover, be it said to the honour of the French Government, received at its hands a decoration which was approved on both sides the Rhine) of the vaccine against diphtheria, and the intimate friend and successor of Pasteur. Dr. Roux has accepted the honour, although hasty scruples of loyalty to his master might for a moment have caused him to hesitate. To a reporter of the *Matin* Dr. Roux has explained—as if explanation were necessary—his decision to accept this decoration. 'Pasteur,' he said, 'was Pasteur. His decoration had an importance and significance quite other than that which mine has or possibly can have. And then, no doubt, Pasteur had his reasons, which I have not—special memories, for instance, of 1870. In a word, he could permit himself to assume towards the German Emperor an attitude that for me is out of the question, for I repeat he had that reason which excuses him—he was Pasteur. What was extremely fine on his part, and was everywhere approved, would be incomprehensible on the part of another, and would be blamed as coming from me.' Nothing could be more proper, and the whole incident does as much honour to the modest but distinguished investigator as to the Emperor who recognises his pre-eminence."

THE *Lancet* publishes the following interesting information received from its correspondent at Rome:—"The week has witnessed one of those pleasant demonstrations of the truly fraternal spirit which scientific investigation evokes and encourages among its accredited votaries. Prof. Grassi, on whom the Royal Society of London conferred the Darwin medal for original work in illustration of the theory of evolution, was entertained at dinner by his colleagues of the Faculty of Sciences of the School of San Pietro in Vincoli and of the Faculty of Medicine. Representatives of all the fields of

research bearing directly or remotely on nature-study and biology took part in congratulating the guest of the evening on his having obtained one of the blue ribbons of scientific merit—among the said representatives being Signor Francesco Brioschi, the eminent mathematician, who presides over the Accademia dei Lincei, and Prof. Semeraro, rector of the University. The first to speak was the veteran professor of chemistry, Signor Stanislao Cannizzaro (himself a former recipient of Royal Society honours), who, in the name of the University of Catania, dwelt on the gratification felt by that seat of learning and shared by all others in Italy at the English recognition of their compatriot. After him came Signor Francesco Todaro, professor of anatomy at the Sapienza, whose speech was dedicated to an exposition of the motives that guide the Royal Society in awarding the Darwinian medal. A third speaker was Prof. Semeraro, rector of the University, who, in the name of the Senatus Academicus, thanked Prof. Grassi for the honour he had conferred on their common *alma mater*. Prof. Grassi's reply was exemplary for its modesty, its recognition of the brotherhood of science, its lofty view of the motives and methods of scientific investigation, and its bright forecast of the future. Referring to the aid, encouragement, and inspiration he had received from his academic colleagues and brethren of the biological laboratory, he dwelt with grateful insistence on the helping hand extended to him by Dr. Baccelli, who was present. The banquet closed in animated conversation, among the topics of which was the *rapprochement*, just signalised in Prof. Grassi's case, between British and Italian research."

THE announcement made last week to the effect that Dr. Thorne Thorne is inspecting the vaccination systems abroad is confirmed by a statement in the *Times* that the Government has a full intention of introducing next Session a Bill to promote free vaccination throughout England on some such plan as obtains on the continent. In order that the Local Government Board should have details of the mode of dealing with this question abroad, a small committee, presided over by Dr. Thorne Thorne, principal medical officer of the Board, has been for the last fortnight in France and Belgium. The committee first visited Paris, where the members were shown over the Institut Vaccinal, affiliated to the municipality of Paris, and afterwards saw the mode of treatment at the Académie de Médecine, where vaccine lymph is distributed gratuitously, after admixture with glycerine, throughout France at the expense of the State. From Paris Dr. Thorne Thorne and his assistant travelled to Brussels, and were there shown over the École de Médecine Vétérinaire, the State Department for Belgium, and afterwards the whole work of vaccination was explained at Dr. Janssen's Vaccination Department under the municipality of Brussels. It was intended to extend the inquiry, but, other medical foreign departments not being quite ready to receive the expert committee, Dr. Thorne Thorne has returned to London. The committee will start again in a couple of weeks for Germany, to examine the question there, and this will be of a more extended nature, as German vaccination depôts are more widespread.

THE trial trip of the torpedo boat *Turbinia*, which has been built by the Marine Steam Turbine Co., Limited, for the purpose of testing the application to marine propulsion of the Hon. Charles Parsons' steam turbine engine, was a really remarkable performance. An account of this trip, which took place on the 15th inst., is given in the *Newcastle Daily Chronicle* for the 17th, from which we make the following extract:—"Several most successful runs were made, and the very high speed of 29·6 knots was attained over the measured mile. It is believed that this is a speed greatly in excess of anything that has ever been previously accomplished by a vessel of the small dimensions of the *Turbinia*, which is only 100 feet in length, 9 feet in beam, and has but 42 tons displacement when fully loaded. Indeed, the speed already attained upon this preliminary trial trip by this small boat nearly approaches the maximum limit of speed so far attained by the largest torpedo boat destroyers, which have more than twice her length and about six times her displacement. Having regard to the fact that this was only a preliminary trial, and that it was shown that there was a considerable reserve of power still to be called upon, it is anticipated that a still higher speed materially in excess of the remarkable result already obtained will eventually be realised. In any case, the obtained results as recorded above, are such as cannot fail to be of extreme interest to all naval architects and marine engineers." A correspondent writes:—"The circumstance that the time-honoured piston engine seems to be beaten for marine propulsion at high speeds by what may be looked on as a more primitive machine, is striking. The *unexpected* speed of all modern torpedo boats is indeed a matter of much interest to the students of even theoretical hydrodynamics."

THE Congrès des Sociétés Savantes will be opened at the Sorbonne, Paris, on April 20, 1897, and will continue in session for three days.

TWO of the three Royal Institution's Christmas lectures, on "Visible and Invisible Light," will be given by Prof. S. P. Thompson, F.R.S., on Tuesday and Thursday afternoons next week.

THE following are among the papers to be read at the meetings of the Society of Arts after Christmas:—The roller boat of M. Bazin, by Émile Gautier; English orchards, by George Gordon; the prevention of fires due to leakage of electricity, by Frederick Bathurst; dairy produce and milk supply, by M. J. R. Dunstan; the transmission of power by alternating electric currents, by W. B. Esson; London water supply, by Prof. Percy F. Frankland, F.R.S.; the chemistry of tea, by David Crole; children's sight, by R. Brudenell Carter; light railways by Everard C. Calthrop; cycling—historical and practical, by George Lacy Hillier.

WE regret to announce the death of Mr. Sidney Waters, a familiar figure at the Royal Astronomical Society, and the author of several interesting papers and charts. He was elected a Fellow of the Society in 1873, in which year he read two papers on the distribution of resolvable and irresolvable nebulæ, and the distribution of the clusters and nebulæ. A paper on the distribution of the stars in the southern hemisphere appeared in the *Monthly Notices* for 1878, and his last work consisted of two very fine maps showing the distribution of the nebulæ and clusters in Dr. Dreyer's Catalogue. Mr. Waters will be sorely missed and deeply regretted by every one who knew him.

A LARGE meteor was seen to pass over New York City from west to east at twenty minutes past five on December 4, while it was still daylight. It was noticed by observers over a wide range of locality, from points nearly twenty miles north, to Staten Island on the south.

THE New York Aquarium at Castle Garden was opened on December 10, with about one hundred species of fish already collected. The galleries will not be entirely finished for a month or two. The stock will be increased in the spring by importations from Florida, Bermuda, California, and elsewhere. Over 11,000 people visited the Aquarium on the opening day.

AFTER conducting the *Zoologist* for exactly twenty years, Mr. J. E. Harting has resigned the editorship owing to increased demands upon his time, and in order to be able to devote himself to the preparation of new editions of some of his books on birds, and to complete an original work on "British Quadrupeds," for which he has been collecting material since 1874. The *Zoologist* was founded in 1843 by the late Edward Newman,

who conducted it until his death in 1876, when Mr. Harting undertook to carry it on. There has thus been but one change in the editorship from its foundation until the present time. Some difficulty has been experienced in finding a competent successor, but it is now announced that the new editor is to be Mr. W. L. Distant.

THE establishment of a big game preserve in British Central Africa has been noted by us upon several occasions. It is now stated that Mr. Alfred Sharpe, the Acting Commissioner, has just issued a series of regulations providing that on and after September 15 last a certain portion of the protectorate shall be "considered and treated as a preserve." In this district "it shall be illegal for any person or persons to shoot, trap, net, or in any way molest any description of wild game within such limits without a written permission from Her Majesty's Commissioner and Consul-General." The regulations further provide for the inspection and, if necessary, withdrawal of any licences granted by the Commissioner, and for the punishment of any breach of the regulations. The tract of country thus reserved is known locally as the Elephant Marsh, and lies on the Shire River above Chiromo. It abounds in buffalo, water buck, and zebra, but unless some such regulations as those just issued were passed it is believed that at the rate at which they were being shot all these animals would have practically disappeared in a few years.

THE *Bulletins* of the Constantinople Meteorological Observatory for March and April contain a study, by Dr. G. Agamennone, of an earthquake felt in the north-west of Asia Minor on April 16. The observations forwarded to the central office are neither numerous nor detailed, and it has not been found possible to determine the origin even approximately. Considerable damage was, however, produced in the village of Amed (lat. 39° 17′ N., long. 29° 15′ E.), and it is probable that the epicentre was not very distant from this place. The shock was felt over a district about 325 km. in diameter, and nearly 80,000 square km. in area. A good time-record was obtained at Constantinople, but the pulsations do not appear to have affected distant pendulums, unless a small movement recorded by the Vicentini microseismograph at Padua can be referred to this earthquake.

THE Pilot Chart of the North Atlantic Ocean for the month of December, issued by the Washington Hydrographic Office, shows that between the Azores and Newfoundland much bad weather was experienced during November, and that fresh to strong gales, principally from the west, followed each other in quick succession over the area between the Grand Banks and the British Isles. The subject of floating derelicts as a danger to navigation is again being brought prominently forward, and the chart plainly shows that the advent of the stormy season has considerably increased the number of the derelicts. Between the south-east coast of the United States and Bermuda the number of abandoned ships, mostly of the schooner build, is particularly noticeable. The ocean was free from ice east of Newfoundland, and the month was remarkable for the small amount of fog reported.

THE last number of the *Mittheilungen von Forschungsreisenden und Gelehrten aus den deutschen Schutzgebieten*, besides a map of the southern part of Togoland with valuable geographical notes appended, contains some important contributions to our knowledge of the meteorology of German possessions in Africa. Observations made at five stations in the Kamerun district during 1894 and 1895 are discussed, one important result being to bring out Debundja (lat. 4° 8′ N., long. 9° 0′ E.) as the wettest station in all Africa, and to place it only second to Cherrapunji in the world, with a mean rainfall of somewhere about 350 inches. As Debundja stands almost at sea-level, the rainfall on the hills above it, exposed as they are to the full effect of the sea-breeze, is probably considerably greater. In September 1895 alone, 74 inches were measured at Debundja, including one record of 7·40 inches in 24 hours. Another paper gives an excellent summary of existing observations of rainfall in German East Africa.

IN connection with the recent important investigations on the artesian waters of Queensland, Mr. Gibb Maitland, of the Geological Survey of that colony, has contributed to its Roya Society a review of the structure of artesian "basins" in North America. Nowhere in this area, with one possible exception, are the water-bearing rocks disposed in those ideal basins that do duty in the common text-book diagram. On the contrary, they have a uniform dip, so as to form only the half of a syncline, and the water, as in Queensland itself, is discharged either into the sea or into important inland springs.

A RECENT number of the *Centralblatt für innere Medicin* contains a notice of some further investigations by A. Pfuhl and K. Walter on the presence of influenza bacilli in the central nervous system. Pfuhl's previous identification of these bacilli in the central nervous system, and his contention that they are always to be found there in cases of influenza which have ended fatally, have received confirmation from these researches. It is, however, pointed out that along with the influenza bacillus large and small streptococci, as well as bacteria, associated with putrefaction, are found. As the colonies of influenza bacteria isolated from the nervous system only develop very sparsely on artificial culture media, and might easily escape recognition in the presence of other bacteria, Messrs. Pfuhl and Walter recommend that their cultivation should be carried out on perfectly clear agar-agar, the condensed water from which has been got rid of by keeping it in a slanting position for two or three days in the incubator, after which human or pigeon's blood is spread over the surface. It is best to discard tubes and employ instead dishes or plates, so as to increase the surface area of the culture material, and the latter should be inoculated by making several streaks with a very fine platinum needle containing the substance to be examined. In this manner all the colonies which subsequently develop can be closely watched under the microscope, and the identification and isolation of the influenza bacillus is materially assisted. That the influenza bacillus, and not the other bacteria found with it, is the actual cause of the disease, has been shown by Nauwerk, who described a case which ended fatally where influenza bacteria and no other varieties were present in the nervous system.

SEEKERS after rare and valuable scientific books should obtain a copy of the Catalogue (No. 165) just issued by Mr. Bernard Quaritch, Piccadilly, London, W.

IN his address as retiring President of the Botanical Society of America, delivered at the last annual meeting, Prof. W. Trelease considered the subject of "botanical opportunity," and pointed out the difference between the conditions which controlled and made possible scientific work, even a few years ago, and those which prevail to-day. The address is printed in full in the *Botanical Gazette*. In it, what is referred to as "botanical opportunity" is considered under the two-fold head of the opportunity of endowed institutions and the opportunity of individual workers. Under the first head the equipment of colleges and research laboratories is passed in critical review, and suggestions are made as to the necessary limitations of such equipment and the provision which may be made for securing its fullest use, both for instruction and investigation. As to the opportunity of the individual, it is shown that breadth of foundation and a well-conceived and studiously followed plan of work, with system in

all of the steps taken, can hardly fail to lead to success in the long run. A considerable portion of the address is given to a consideration of the subject of publication, as viewed from the standpoint of the administrator of a research institution and the student seeking a medium for the publication of the results of his work.

THE additions to the Zoological Society's Gardens during the past week include a Rufous Rat Kangaroo (*Æpyprymnus rufescens*) from New South Wales, presented by Captain N. Allen; a —— Squirrel (*Sciurus*, sp. inc.) from Java, presented by Captain G. C. Candy, ; a Levaillant's Cynictis (*Cynictis levaillanti*) from South Africa, presented by Mr. Joseph Francis; eleven Harvest Mice (*Mus minutus*) from Surrey, presented by Captain Salvin; three Herring Gulls (*Larus argentatus*), British, presented by Mr. J. W. Wilkes; two Black-bellied Sand Grouse (*Pterocles arenarius*) from Spain, presented by Mr. Gerard S. Torrens; two Nicobar Pigeons (*Calœnas nicobarica*) from the Indian Archipelago, a Canarian Pigeon (*Columba laurivora*) from the Canary Islands, deposited; three Varied Field Rats (*Isomys variegatus*), three Larger Egyptian Gerbilles (*Gerbillus pyramidum*), nine Lesser Egyptian Gerbilles (*Gerbillus ægyptius*), three Long-eared Hedgehogs (*Erinaceus auritus*), forty-six Egyptian Geckos (*Tarentola annularis*), five Fan-footed Geckos (*Ptyodactylus lobatus*), a Grey Monitor (*Varanus griseus*), five Horned Cerastes (*Cerastes cornutus*), six Square-marked Toads (*Bufo regularis*) from Egypt, received in exchange.

OUR ASTRONOMICAL COLUMN.

MOUNTAIN OBSERVATORIES.—The great increase in size of the apertures of instruments for use in astronomical research, has led astronomers to look further afield for spots on the earth's surface where the atmospheric conditions are most favourable for the work to be satisfactorily accomplished. The neighbourhood of large towns is now generally conceded to be no place for a big refractor or reflector, although occasionally a very fine night may be luckily secured. For the study of planetary details, and the taking of long-exposure photographs, and other kinds of work, a steady atmosphere is a necessary essential. In order that the stellar images may be still and devoid of that flickering and movement which is only of too common an occurrence, the atmosphere itself must be to a certain extent in stable equilibrium, and the layers at rest one above the other. There are not, however, many places where these conditions are fulfilled. In fact there are no such spots where perfect stillness reigns supreme, but some are better than others in this respect. The question then is, where are such localities for which the astronomer, armed with a powerful instrument, may make his stand? We may answer this question by saying that up to the present time very few have been found, although search is more or less continuously being made. In America we know that some observers are at work with their instruments of large power, in an atmosphere which is at times almost perfect. Not only is the air in that quiet state of equilibrium that is so necessary, but they are blessed with long spells of continuous fine weather. Any one who wishes to find out for himself what are the essentials to "good seeing," how far we have progressed in the construction of mountain observatories, and, further, where those already set up are situated, cannot do better than consult Prof. Holden's contribution to the Smithsonian Miscellaneous Collection. The writer there has massed together a great amount of material concerning those situated in America and Europe, and has also added greatly to the description of them by the insertion of numerous illustrations. We may, however, mention that meteorological stations at high or moderately high altitudes are also included; but these must, as we all know, be forerunners of those equipped for the special study of astronomy.

OBSERVATIONS OF SATURN.—In the study of planetary detail our atmosphere plays a most important *rôle*, and, as we have said in the preceding note, some places are more suitable for such observations than others. Some very interesting observations given in the *Astronomischen Nachrichten* (No. 3390) serve to show that the same observer, making similar observations at two different stations, not of course simultaneously, finds really marked differences in powers of seeing. Herr A. Anton Wonaszek records his visit to the Manora Observatory, where Herr L. Brunner is at work. The objects looked at were the planets Mercury, Venus, Mars and Saturn, and Herr Wonaszek expresses astonishment at the great amount of detail that can be observed in the pure air of Lussin. As regards Saturn, the markings looked at by both these observers were the dark and light spots situated on the disc. Both made independent drawings of these (illustrations of which are given in the *Astronomischen Nachrichten* referred to), with the result that in most respects they are very similar. Herr Wonaszek, however, finds out that Herr Brunner's eyes are capable of detecting more quickly the bright spots, while his own are more sensitive to those of a darker shade. With a 7-inch refractor situated at Kis-Kartal, he says that his numerous observations of Saturn do not show the great amount of detail that he recorded at Lussinpiccolo, although, by good atmospheric conditions, he is able to see a great deal. From the drawings which he gives, it is seen at a glance that the spots referred to above are seen at his observatory somewhat with difficulty, and are not so clearly defined as was the case at Lussinpiccolo. Both sets of observations, however, give one a good idea of these curious spots, which are not restricted alone to the equatorial regions, but occur towards the poles. From these drawings, however, no dark spot attains any great distance from the equator. The observations referred to above were made during the month of August last.

KARLSRUHE MERIDIAN OBSERVATIONS.—The fifth volume of the "Publication of the Grossherzoglichen Observatory of Karlsruhe" contains the observations made with the meridian circle, and includes the positions of all these stars down to the 8th magnitude in the zone $-0°$ to $-7°$, which were not observed in the preceding volume. The observations were made by Prof. Valentiner and Dr. Ristenpart, and number 8300. Volume iv. of the same publication contained 13,800 observations, so that the total number amounts now to 22,100, thus concluding the work in this zone. The programme was to observe each star six times, and this has been carried out with only a very few exceptions, the number of stars on the working list being 2700. The reduction of the observations was done throughout by Prof. Valentiner and Dr. Ristenpart.

At the completion of the work a thorough investigation of the division errors of the circle was made. This undertaking could not, as we are informed, be done earlier, as the *personnel* of the observatory was too limited in numbers.

The three sections into which the volume is divided are (1) observations with the meridian circle; (2) elements for the reduction of these observations; and (3) mean places of the southern stars observed in the years 1892-94, reduced to the epoch 1885·0.

In the preface Prof. Valentiner refers at some length to the late Ernst von Rebeur-Paschwitz, who was connected with the observatory from July 1884. Allusion is also made to the fact that this "Publication" is the last that will proceed from the Karlsruhe Observatory.

The new building that is being erected on the Königstuhl at Heidelberg will, no doubt, be soon ready for work; and being under better conditions in many respects, Prof. Valentiner will be able to continue his work with renewed zeal.

THE WESTERN AUSTRALIA GOVERNMENT OBSERVATORY.—The decision of the Government of Western Australia to erect an observatory at Perth, at a cost of about 5000*l.*, was announced in these columns nearly a year ago (vol. liii. p. 280). The *Daily Chronicle* now notes that the Government Astronomer, Mr. W. Ernest Cooke, during his recent stay in England, was engaged in the purchase and inspection of the necessary instruments. The two principal instruments will be an astrographic equatorial and transit circle, in addition to which the observatory will also probably be furnished with a cœlostat. Mr. Cooke proposes to devote his energies mainly to the observation of fundamental southern stars. He will, in addition, take charge of the meteorology of the colony. From each of the meteorological stations a report will be telegraphed daily to the observatory, and with the help of this and other information supplied by the Eastern Colonies, a daily weather map of the entire continent will be issued, together with forecasts of the coming weather.

OPENING OF NEW LABORATORIES AT UNIVERSITY COLLEGE, LIVERPOOL.

THE great interest which the manufacturers of Liverpool take in the University College of that city was again exemplified by the opening of the new William Gossage laboratories a few days ago, briefly referred to in our Educational Intelligence last week. Since the college was founded, it has had the ready and full support of the manufacturers and traders of Liverpool and the district around, the result being that today it is in the front rank of institutions for higher education. With well-equipped laboratories, and a strong professoriate, the college possesses exceptional opportunities for study and research; and the work accomplished in it has done much to advance the arts as well as the sciences. The teaching course, which extends over four years, not only aims at training students for manufacturing pursuits, but also to carry out independent investigations.

The first section of the chemical department of the college was opened in May 1886. But the main laboratories, the most important of all, were not at that time proceeded with, partly owing to lack of funds, and partly because a portion of the site, the whole of which was given by the Corporation of Liverpool, was not then vacant, and could not be transferred to the college until later. In the early years the advanced students were necessarily few in number, and there was sufficient accommodation for them as well as for much larger junior classes; but by the year 1893 the want of a complete laboratory for the whole of the special laboratory students was seriously felt.

In these circumstances Mr. F. H. Gossage and Mr. T. Sutton Timmis generously undertook jointly to build and fit up a further section of the building, including the largest of the main laboratories and rooms below, at a cost of 7000*l.*, and to present them to the college as a memorial of the late Mr. William Gossage. Other portions of the buildings are being erected by public subscription, the list being headed by donations of 1000*l.* each from Sir John T. Brunner, M.P., Mr. E. K. Muspratt, and Messrs. Lever Brothers.

Mr. William Gossage, whose name is enshrined in the new laboratories, was one of the most fertile inventors of this century. His work was mainly chemical, and before his death in 1877 he possessed no less than sixty-three patented processes. In the early days of the soda industry, the hydrochloric acid gas, which is evolved from common salt for the production of sulphate of soda, was poured into the air in enormous volumes, to the destruction of vegetable and injury of animal life. In 1863 the Earl of Derby was instrumental in passing into law the Alkali Act which compels manufacturers to condense all except a very small fraction of the hydrochloric acid gas which they produce. It was William Gossage who rendered this legislation practicable by inventing the tall stone condensing towers which are so prominent a feature of the landscape in every Leblanc alkali works' district, and by means of which what was before worse than wasted is turned into a source of considerable profit to the manufacturers.

In 1838 he was engaged in experiments for the recovery of sulphur lost in the alkali waste of the Leblanc process, and also for the manufacture of soda from sodium sulphide. It was at this time that he demonstrated that calcium sulphide, and also sodium sulphide in solution, are decomposed by the action of dilute carbonic acid produced in lime kilns. In 1854 he produced silicate of soda or soluble glass by fusing sand with soda. He also utilised the red liquors from carbonate of soda manufacture, which were at that time an almost waste product, producing from them caustic soda, which was for years the only caustic soda made, and was employed to facilitate the manufacture of soap. He thus introduced what has now become a large and important industry in caustic alkali. In many other directions his inventive mind found occasional diversion, and of him it may be truly said that, although he was a successful manufacturer, he spent his mental energy and his means seeking out many inventions which benefited others rather than himself.

The new buildings, opened on December 12, include a large laboratory 60 feet by 32 feet, with benches fitted up for forty-four advanced students, an adjacent room provided with a new form of heated sand bath and other appliances for the service of the main laboratory, and, in the basement, an additional lecture room to seat seventy or eighty, a preparation room, and a gas analysis room. These five rooms, which are lined with ivory glazed bricks, constitute the "William Gossage" laboratories.

The other new buildings are a metallurgical laboratory, with furnaces and other equipment, an important addition to the research laboratory, a store for apparatus and chemicals, a dynamo room, electric-accumulator room and a heating chamber.

Beyond a number of minor improvements in the main laboratory, the benches do not essentially differ from those in some other similar laboratories except in one important respect, that the half-closed chambers placed in the middle of each bench have a really efficient draught which carries away all fumes from small operations without allowing any to escape into the room. This result is attained by carrying the whole ventilation of the room, which normally amounts to 125,000 cubic feet per hour, through these students' fume chambers and the larger chambers on either wall; the foul air passes from these hoods down to a wide subterranean channel ending at the base of a tall up-cast shaft, where a coke fire maintains a strong draught; by no other way can air escape from the laboratory, while a fan forces washed and warmed fresh air through flues and gratings in the walls into the room, so as to maintain a constant pressure during the working day.

The laboratories will be opened to students on January 7, 1897, and the committee will be glad to receive further donations to enable them to finish the buildings, and furnish the necessary equipment.

THE ANTHROPOLOGICAL HISTORY OF SOUTHERN RUSSIA.

IN continuing his ethnographic history of the region between the Dniester and the Caspian in the *Bulletins de la Société d'Anthropologie*, vii. (4 sér.), 1896, M. Zaborowski commences by criticising Sergi's assertion that "the first colonists of Southern Russia came from the Mediterranean." The enthusiastic Italian anthropologist recognised skulls of the type of his Mediterranean race from ancient graves in several parts of Russia, but Zaborowski contends that he has not paid sufficient attention to the dates of the finds, and that he has neglected the culture evidence. The author reserves the term Aryan to the tall blond dolichocephalic race, that is solely of European origin, which is not the case for the brown dolichocephalic Mediterranean race or the Celto-slavic type. Aryan languages are spoken in Europe where the brown brachycephals and dolichocephals have never penetrated, at least until our epoch; but there are no people with an Aryan language who have not come into contact with the fair race.

In the most ancient graves of the bronze age, Neolithic dolichocephals are still generally to be found, but before the Scythian epoch there was a mingling of brachycephals, perhaps partly through commercial relations and partly from women captured in war. The original home of the Scythians was to the east of the Caspian. The finds in the Scythian tombs exactly correspond to the description given by Herodotus of their neighbours, the allied Massagetes, except that iron is not quite unknown. The Thyssagetes, Tyregetes, Getes and Dacians, arose from the Scythians and Massagetes, descendants from the Getes and Dacians, still exist among the Roumanians, having harsh black hair and a yellow-brown complexion. In Scythia, Herodotus mentions the large nation of the indigenous, nomadic Budins, who "have remarkably blue eyes and red hair." These may be the ancestors of the Finns, at all events they formed a contrast to the Scythians, to whom Hippocrates attributed a short stature and a brown skin.

The Scythian period was terminated by the arrival of the Goths in the second century A.D. Strabo does not know of them, Tacitus mentions their occupying the shores of the Baltic between the Elbe and the Vistula. Later they came down the latter river to the Black Sea, and reached the lower Danube; at the commencement of the third century this enterprising and warlike nation touched the eastern borders of the Roman empire. The Goths were described as very large, of fine appearance, fair hair, milk-white skin, with great moral energy, modest, and very strong. They spoke a German dialect, and were even in possession of the primitive runic alphabet. The arrival of the Goths at the Black Sea is a return of the European blonds to a region where the brown Asiatic Scythians had reigned as masters for centuries.

M. Zaborowski evidently believes that the Aryan language arose about the Black Sea. He, with Broca and others, accepts the tradition that the Cymbri of Jutland were the descendants of

the Cimbrians of the Cimmerian Bosphorus, driven to the west of Europe by the Scythian invasion in the seventh century B.C. These Cymbrians had already had relations with the Greek world, for the Greeks had established colonies and introduced metals and the cultivation of the soil in Southern Russia before the arrival of the Scythians, and they may be regarded as the importers of the dialect from which the German languages arose. They were of the same race as the Neolithic blonds.

The Goths were driven away from the northern borders of the Black Sea by the Huns before the end of the fourth century; but though they remained during only two centuries, traces of their stay have been discovered.

The Alains, mentioned by authors in the first century A.D., were a blond people mixed with Medes, and possibly with the Scythian Massagetes. The Ossethes sprang from these Scythian Alains, who were driven into the Caucasus after the Gothic period by the pressure of the Huns. Thus the Ossethes are essentially Aryans and Europeans, despite the Iranian and Asiatic origin of their language, these originally blond Europeans, have been intimately mingled with Scythians, and later with other Caucasians, mostly browns and brachycephals. M. Kovalewsky states that among the Ossethes, when a bride enters for the first time her husband's house, she is greeted with "Prosperity! prosperity! nine boys and a girl with blue eyes." The latter wish could never arise amongst a brown population. In his work "Droit Coutumier Osséthien" (1893), Kovalewsky details numerous customs which, as Zaborowski points out, abundantly confirm the essentially European and Aryan origin of this nation; and the former author compares them with those of the Greeks of Homer, the Germans of Tacitus, and with the Romans, such, for example, as the cult of the hearth-fire, household arrangements, marriage ceremonies, and burial customs.

The Armenians, like the Ossethes, are a people with their original characters modified. They were also blond, at least in great part, and even now 11 per cent. are blonds according to Chantre.

In the Hindu Kush there are many traces of a fair race, and Zaborowski enters into a comparison of the Kafirs with the Ossethes, which tends to show that they are closely related.

THE HORN EXPEDITION TO CENTRAL AUSTRALIA.

THE Report on the work of the Horn Scientific Expedition to Central Australia has now been completed. It is published in four parts, the first of which is devoted to the narrative and summary of scientific results, while the three remaining parts deal respectively with zoology, geology and botany, and anthropology. The zoological results were reviewed in NATURE a short time ago (vol. liv. p. 241), and we propose to deal with the part on anthropology in a future issue. For the present we confine ourselves to summarising the knowledge gained of the geology and botany of the region explored, prefacing the synopsis with a statement of the inception and objects of the expedition, and of the region traversed, this introductory matter being based upon the Narrative.

Objects of the Expedition.

Mr. W. A. Horn, who defrayed the cost of the expedition to Central Australia, and through whose generosity the Report has been published, deserves the gratitude of men of science. The results which he has been the means of obtaining are most valuable contributions to the knowledge of the natural history of a little-known region; and by the accumulation of these facts, gained by direct observation, many perplexing questions will be elucidated. One of these questions is referred to by Mr. Horn in a brief introduction to the Narrative. For some time the opinion has been held that when the Australian continent was submerged the elevated portions of the McDonnell Range in Central Australia existed as an island, and that consequently older forms of life might be found in the more inaccessible parts. The scientific exploration of this belt of country was, therefore, much desired by men of science, and when Mr. Horn expressed his intention to organise and equip an exploring party, the scheme was received with great favour. In order to secure the services of the best men in Australia, the Premiers of the principal colonies were asked to nominate scientific representatives. As a result, Prof. Baldwin Spencer, Mr. J. Alexander Watt, Prof. Ralph Tate, and Dr. Edward Stirling joined the expedition, and Mr. C. A. Winnecke was chosen as surveyor and meteorologist.

The objects of the expedition as set down in the articles under which the members started were:—The scientific examination of the country from Oodnadatta to the McDonnell Range; the collection of specimens illustrative of the fauna, flora, and geological structure and mineralogical resources of that region, and the illustration by photography of any remarkable natural features of the country traversed; the securing of photographs of the aborigines in their primitive state, the collection of information as to their manners, customs, and language, and the reproduction of their mural paintings. The expedition started in May 1894, and returned in August of the same year, burdened with the records and the photographic spoil of the region which the members went out to see.

The McDonnell Ranges.

The McDonnell Ranges are in the very centre of Australia, they are barren and rugged in the extreme, rise to an altitude of nearly 5000 feet above sea-level, while the country surrounding them has an altitude of about 2000 feet, sloping away on every side towards the coast, 1000 miles distant. The mountains are at the head of the river Finke, and for this region, including the valley of the Finke, the name of Larapintine has been adopted from the native name of the Finke, "Larapinta." It was over this area that most of the explorations were conducted.

The general editor of the Report on the work of the expedition is Prof. Baldwin Spencer, who is also the author of the Narrative. Without entering into too many details, Prof. Spencer summarises, in a more or less popular form, in this part of the report, the work accomplished, and gives a good idea of the nature of the country through which the expedition passed.

Nature of the Country traversed.

It is usual to speak of the whole interior of Australia as a desert or Eremian country, but Prof. Spencer shows that this name as applied to the whole area is very misleading. It is true that over wide areas extending especially over the western half of the interior there spead out sandhills and flats covered with Mulga scrub or "Porcupine" grass, which may justly be described as desert, but in addition to this there is a vast track of country watered by streams which at varying intervals of time are swollen with heavy floods which spread out over wide tracts, and for a time transform the whole country into a land covered with a luxuriant growth of vegetation. To this part of the continent the name of the Australian Steppes has been applied. The Lower Steppes extend over the area occupied by the great Cretaceous formation with its alternating stony or gibber plains, loamy flats, and low-lying terraced hills capped with Desert Limestone. At Lake Eyre the land is 39 feet below sea-level, and gradually rises to a height of 1000 feet at its northern limit. What are termed the Higher Steppes are characterised by high ridges of Ordovician and Pre-Cambrian rocks which stretch across the centre of the continent from east to west for some 400 miles. The average elevation of these Higher Steppes may be taken as about 2000 feet, and above them the higher peaks of the ridges rise for some 2500 feet more.

Prof. Spencer devotes two chapters in his Narrative to the country belonging to the Lower Steppes, two to the Higher Steppes, and one to the Desert Region. The gibber plains to which he refers consist of flat surfaces covered with a layer of purple-brown stones, varying in size from an inch to perhaps a foot in diameter, and all made smooth by the constant wearing away of wind-borne sand-grains. Judging from the description, and the views which illustrate it, nothing could be more desolate than a gibber plain when everything is bare and dry. Throughout this district the low flat-topped desert hills have a thin capping of hard chalcedonised sandstone, and it is by the disintegration of this rock that the gibbers or stones have been produced. The stony gibber plains merge constantly into loamy plains covered with poor scrub, but on which the gibbers are wanting. It is suggested that these loamy plains occupy areas on which the Upper Cretaceous rocks are not capped with the hard chalcedonised Desert Sandstone, and where, therefore, no gibbers have been formed.

Colours of Animals.

Some interesting remarks are made by Prof. Spencer on the subject of protective colouration. Prof. Spencer has collected animals in Central Australia, both in the dry season and in the

wet season, and his study of the fauna leads him to the following conclusions.

(1) That in the dry season, when food is scarce and the sum total of activities is at its lowest point, the various animals, such as frogs and lizards, are dull-coloured, but that this dull colouration has not of necessity (as in the case of *Amphibolorus barbatus*) any definite relation to the environment, though it is often in general accord with it. (2) That in the rainy season, when food is plentiful and the sum total of the activities is at the highest point, various animals are highly coloured, but that this often brilliant colouration has nothing to do either with choice of partners (reaching its climax after pairing has taken place) or with protective colouration—sometimes even it renders the animal more conspicuous.

Limits of space prevent us from summarising any other points of interest from Prof. Spencer's most attractive Narrative. For a more detailed notice of the zoological collections and conclusions, we must refer our readers to the review which appeared in these columns last July (vol. liv. p. 241). We must mention, however, that the narrative is illustrated by eleven plates (splendidly reproduced from photographs) and seven figures in the text. Among the objects and views depicted upon the plates is a striking natural pillar of sandstone—Chamber Pillar—rising solitary among the sandhills; Ayers' Rock—a huge dome-shaped monolith, brilliant Venetian red in colour, and one of the most striking objects in Central Australia; several wonderful gorges among the McDonnell Range and Mount Olga. These picturesque views add to the interest of a well-written narrative.

General Geological Features.

We come now to the part of the Report referring to the geological and botanical results of the expedition, and here again we think that the valuable work accomplished will be best made known by summarising the leading features. The first section of the third volume opens with a general outline of the physical geography of Central Australia, by Prof. Ralph Tate and Mr. J. A. Watt. The subject is dealt with under seven heads, viz. mountains, rivers, gorges and gaps, lakes, claypans, stony plains, and sandhills. The same authors contribute a description of the geological features of the portion of Central Australia examined by them, embracing the country lying between Oodnadatta on the south, and the McDonnell Ranges on the north.

Under headings bearing the names of the geological systems to which the different series of rocks are assigned, an account is given of the general geological features, the extent, thickness, mineralogical composition, petrological characters, and fossiliferous contents of the various rocks. Beginning with the Pre-Cambrian system, the conclusions of previous observers as to the age of the rocks of the McDonnell Ranges, which exhibit a high degree of metamorphism, are summarised. These rocks have been described as Archæan and Azoic, but the authors conclude from the fact that a very strong unconformity separates the rocks from the Lower Silurian Group, that they must be either Cambrian or Pre-Cambrian, and reasons are given for favouring the latter alternative. The evidence obtained points to much of the metamorphic group having had an eruptive origin, whereas the Cambrian rocks of Australia, so far as at present known, are entirely sedimentary. In the region examined (from Oodnadatta to the McDonnell Ranges) Cambrian rocks are held not to be represented. Almost all the strata lying between Mount Burrell Cattle Station on the south, and the McDonnell Ranges on the north, are included by the authors in the Ordovician system.

The superstructure of the lowest levels around Lake Eyre have long been known to be argillaceous, and to contain marine fossils, as at Mount Margaret, Primrose Springs, and Dalhousie. The fauna was at first referred to the Jurassic period, but has in late years been recognised as contemporaneous with that of the Rolling Downs series, regarded as Upper Cretaceous, of Queensland. It has generally been held that the source of supply of the natural artesian wells on the west side of Lake Eyre was derived from tropical rains in Queensland absorbed by Cretaceous outcrops, and that the issue of these waters was along the line of junction of the Cretaceous water-bearing beds with the Palæozoic rocks on the west margin of Lake Eyre. But the now-ascertained far-northerly extension of the Cretaceous rocks, and the replacement of the prevailing argillaceous condition by sandy strata towards the northern boundary make it probable that the source is, after all, of local origin. Thus, the Finke River from Henbury to Crown Point flows approximately along the junction of the Cretaceous arenaceous beds and the impervious Ordovician limestones; so also do the Goyder and Lilla Creeks, particularly towards their sources. Moreover, the Cretaceous beds have in the main a slight southerly inclination. It is, therefore, highly probable that they do absorb some of the flood-waters of those river-channels, and conduct them to considerable depths in the depressed area margining Lake Eyre; whilst in no instance do the subterranean waters issue at the surface at a level so high as that of their conjectural intake. The phenomenon of extinct mound-springs, as at Dalhousie, may be explained by the circumstance of a diminished supply; in other words, that the level of saturation has fallen below the level of discharge as a consequence of the desiccation of the climate since Pliocene times.

A hard flinty quartzite or chalcedonised sandstone, varying up to fifty feet in thickness, forms the topmost bed of the Rolling Down series, and is referred to as the Desert Sandstone. The Rolling Down series is held to be akin to the European Upper Cretaceous, and the Desert Sandstone is designated Supra-Cretaceous, the palæontological difference between the two being very slight. The Desert Sandstone of Central Australia, on account of its attachment to the Upper Cretaceous, and by the occurrence of marine Mollusca of Cretaceous age (at Lake Frome well-sinkings), is regarded as coeval with the Desert Sandstone of Queensland, which, by its intercalated marine sediments, is proved to be Cretaceous; though separated unconformably from the Rolling Down series (Upper Cretaceous). The phytiferous beds, which underlie marine Eocene in Victoria and South Australia, and are conformable with them, are considered as Pre-Eocene.

As to the origin of the silicification of the Desert Sandstone, in the first place, the obsidian bombs and agates which occur on the Desert Sandstone plateaus and their slopes could not have been transported there by water, unless in the form of ice (an hypothesis incompatible with the coordinate features). The origin of the Desert Sandstone breccia was certainly not due to fracture of the original bed by failure of support arising from denuding action, but might have been caused by a lava-flow or the deposition of highly-heated volcanic ashes when saturated with water. The obsidian bombs demand volcanic action, and agates are not infrequently associated with volcanic ejectamenta; whilst the silicates of the ash-beds or lava under chemical action would furnish silicated waters as a source of the chalcedonising action on the underlying rock-surfaces. The development of agates within the volcanic material was only another phase of siliceous precipitation. Of this suppositious volcanic formation all that remains are the agates and the obsidian bombs. The theory may seem wild, because of the widespread silicification, and the absence over its area of any traces of actual volcanic outbursts; nevertheless, it is held that no other explanation accounting for the several phenomena appears admissible.

Excepting the silt deposits of the present water-ways and the widespread sand-plains, the only Tertiary deposits of any significance are those which indicate a former water-flow of vaster volumes than at present. These signs are chiefly in the form of gravels, more or less consolidated, through which the present water-channels have cut their way, or in the form of terraces margining the valley-plains through which now flow relatively diminutive creeks. These facts demonstrate that high pluvial conditions once prevailed; and, in consequence, perennial flows in the river-channels of this region were maintained, which, discharging into Lake Eyre, and supplemented by an Artesian supply in and around it, produced an inland sea of fresh water, inhabited by alligators (*Pallimnarchus pollens*) and turtles, and on its marshy margin dwelt *Diprotodon* and its fossil associates. Inferentially the date of formation of these gravels and river-terraces is coeval with the existence of *Diprotodon*, whose extinction was due to those physical causes which destroyed its habitats, and gave Central Australia its present rigorously dry climate. The marsupial life of this period, on comparison with that which replaced it, indicates a high antiquity in the number of extinct genera, and the very high percentage of extinct species.

Gold in the McDonnell Ranges.

The highly metamorphic character of the Pre-Cambrian rocks of the McDonnell Ranges, their greatly disturbed state, their extensive development, and, lastly, the presence of numerous

intrusive masses varying much in composition, are all circumstances favourable to the development of mineral deposits in them. Gold is the only mineral that has been found in payable quantities in these ranges, and that only in a very limited area of about fifty square miles, situated seventy to eighty miles E.N.E. of Alice Springs, on the Arltunga or Paddy's Hole goldfield. Although, as just stated, gold in payable quantities has been found on the above-mentioned goldfield, yet alluvial gold in small quantities has been found also near Winnecke's Depôt, Bald Hill, and in some of the gullies in the Georgina Range.

The most important auriferous quartz reefs have a prevailing due north and south trend, and their gold contents show a remarkable uniformity. The country-rock includes metamorphic gneisses and mica schists, intruded by eruptive dykes. Where not absolutely vertical the underlay is almost without exception to the west, and varies from 5° to 10°. The outcrops of these reefs, which are not, as a rule, traceable for any great distance, vary in width from four inches to two feet six inches, while at the bottom of trenches and shafts the width varies from three inches up to four feet six inches. Taking the average of ten reefs, the width at the surface was found to be twelve inches, while at an average depth of twenty-one feet it was fifteen inches. Gold is contained not only in the veinstone, but occasionally and in a less degree in the selvage also, on one or both sides of the reef. In nearly all the reefs the gold is associated with gossary quartz, some of the best results being obtained from a spongy siliceous matrix, which crumbles easily when subjected to pressure.

The lithological specimens gathered during the Horn Expedition included examples of a number of interesting rocks. The microscopical structure of some of the eruptive, and a few of the most typical of the metamorphic varieties, are briefly described by Mr. W. F. Smeeth and Mr. J. A. Watt, their paper being illustrated by four plates. The Palæontology of the expedition forms the subject of a separate contribution by Prof. Ralph Tate, who also deals with the botany.

Origin of the Flora.

The route traversed by the main body of the expedition practically circumscribes what has been termed the Larapintine region. The Larapintine flora is fully described, Prof. Tate taking in turn the general physiography and boundaries of the region, botanical characteristics, origin of the flora, previous explorations, enumeration of the flowering plants and vascular cryptogams, and diagnosis of new genus and species. The flora of the central "Eremian region" is briefly described in a separate paper.

The distribution of the constituent elements of the Larapintine flora and their exoteric relationships, taken in conjunction with the physiographic changes that have taken place within the area, lead to the conclusions that:—

(1) The Larapintine table-land was isolated, except perhaps in a northerly direction, during the deposition of the marine sediments constituting the Rolling Downs system (Upper Cretaceous).

(2) The marine submergence was replaced by a lacustrine area during the deposition of the Desert Sandstone (Supra-Cretaceous).

(3) A cosmopolitan flora prevailed at this period, which continued into Paleocene times.

(4) The area occupied by the lacustrine area of the Desert Sandstone period was somewhat reduced, yet high pluvial conditions continued into Pliocene times.

(5) In Post-Pliocene times a high state of desiccation was reached, which has continued till to-day. The cosmopolitan flora became largely extinct, and its place occupied by an Oriental immigration, more especially over the previously-submerged areas.

A short description, by Mr. J. H. Maiden, of the vegetable exudations collected during the expedition, concludes the volume.

We have had to content ourselves with a sketch of the work of the expedition and of the conclusions arrived at from the knowledge gained. This abridgment will suffice, however, to show the value of the results obtained in geology and botany; and we need only point to the volumes themselves as monuments to Mr. Horn's generosity, and to the industry of the members of the expedition organised by him.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE Paris University Council has resolved to consider the institution of a degree which foreign students might take away with them as a proof of their studies and acquirements in Paris.

THE officers for the Oxford University Junior Scientific Club for next term will be as follows:—President: A. W. Brown (Christ Church). Treasurer: A. E. Boycott (Oriel). Editor: A. R. Wilson (Wadham). Chemical Secretary: W. P. Billinghurst (St. John's). Biological Secretary: J. E. H. Sawyer (Christ Church). Committee: R. A. Buddicom (Keble); E. H. Hunt (Balliol); D. Meinertzhagen (New Coll.).

AT the inauguration of the Lyons University, the Rector, M. Compayre, announced a donation to the university of 4000*l.* from M. Auguste Falcouz, a Lyons banker. The *British Medical Journal* states that the interest of this sum is to be disposed of as follows:—Every two years a prize of 40*l.* sterling will be given to the students of each of the four faculties—literature, science, law, and medicine—who write the best essay on a current subject. The subject of the essay will be chosen by the Council of the Lyons University a year in advance. Every two years instruments for the science and medical faculties will also be bought. When fifty years have elapsed, the Lyons University will have entire control over the capital in order to be able to meet the demands of scientific progress.

DR. G. H. BRYAN, F.R.S., has been appointed professor of pure and applied mathematics in the University College of North Wales, at Bangor. Dr. Bryan graduated at Cambridge in 1886 as Fifth Wrangler. In 1888 he was Smith's Prizeman, his essay being published by the Royal Society; he was then elected Fellow of Peterhouse. In 1895 he became Fellow of the Royal Society, and received the degree of Doctor of Science of Cambridge University. Dr. Bryan has been appointed one of the examiners for Part II. of the Mathematical Tripos (1897). He is the author of a valuable report to the British Association on the "Present State of our Knowledge of Thermodynamics," and of several other important papers on mathematics and mathematical physics.

MAGDALEN COLLEGE, Oxford, has just elected Mr. R. W. T. Günther to an official fellowship as tutor in natural science. Mr. Günther, who is the son of Dr. Albert Günther, F.R.S., so well and long known in the scientific world, has had a distinguished career at Oxford. He was elected to a demyship in natural science at Magdalen in 1888, from University College School. He took a first class in morphology in 1892, was appointed University student of biology at Naples in 1893, and Royal Geographical student in 1895, and has been first lecturer and then tutor at Magdalen since 1894. He has made several contributions to Prof. Ray Lankester's very interesting "Linacre Reports," and he read a paper at the British Association meeting last summer. It may be noted that Magdalen has already this term elected a demy and an exhibitioner in biology, the former coming from the Charterhouse, the latter being a pupil of Prof. Weldon at University College.

THE following are among recent announcements:—Dr. Surmont to be professor of hygiene at Lille; Dr. P. V. Lichtenfels to be full professor of mathematics in the Polytechnic Institute at Graz; Dr. Edler to be associate professor of agriculture in the University of Jena; Dr. E. Pringsheim to a professorship of physics in Berlin University; and Dr. Karl Friedheim to a professorship of chemistry; Dr. Kalischer to be professor of physics at the Technical High School of Berlin-Charlottenburg; Dr. Autenrieth, privat-docent of medical chemistry at Freiburg i.B., to be provisional successor to Prof. Baumanns; Dr. J. Kurschak to be associate professor of mathematics at the Technical High School in Budapest; Dr. Anton Pestalozzi to be assistant in the Zürich Botanical Museum; Prof. Blass to be full professor of geology at Innsbruck. Dr. Szadeczky has been invited to become associate professor of geology at Klausenburg; and Prof. Allé, professor of mathematics in the German Technical High School at Prague, has been called to the Technical High School at Vienna.

THE conference of headmasters was opened at Rugby on Tuesday, and was largely attended. After a long discussion a resolution declaring the organisation of secondary education to be a matter of pressing necessity, with which the Government should be urged to deal in the next Session of Parliament, was carried, with a rider expressing the desire of the conference to

co-operate with other educational bodies. In moving "That the new regulations for Woolwich examinations will not be satisfactory unless the number of subjects a candidate can take up is diminished by at least one, and that a heavy one, below the present number," the Rev. Dr. James said the Army curriculum afforded no education at all. It was, from the literary point of view, a failure, and from the scientific point of view was poor and inadequate. The incessant and irritating changes were a grave detriment to the intellectual development of the candidates. The result of these changes was especially felt in the department of science, and it was made impossible to give a really valuable scientific training. Under the old system nine was the maximum number of subjects. Now a boy was to be allowed to take up ten subjects, and the amount of mathematics in Class I. had been very largely increased, while a third alternative subject had been added which was beyond the reading required by the scholarship standard for mathematics at the Universities. Dr. James's resolution fell through, but the following were adopted in its place:—(1) That the new regulations for Woolwich examinations involve a disastrous increase of the burden of a curriculum which is already too heavy for candidates of the required age. (2) That it is not desirable that any such changes as are proposed should be made in regulations which have been only recently established, and which have enabled Woolwich and Sandhurst candidates to be generally prepared together, and that the committee be instructed to urge the views of the conference on the military authorities.

SCIENTIFIC SERIALS.

American Journal of Science, December.—*Archelon Ischyros*, a new gigantic Cryptodire Testudinate from the Fort Pierre Cretaceous of South Dakota, by G. R. Wieland. This testudinate is closely allied to the genus Protostega. All the large bones were found in place, and the skeleton was almost complete. The ribs, which average 1 m. in length, are remarkable for their distal increase in thickness. The cervical centra are very heavy and strong bodies, and indicate a neck of enormous strength. The humerus measures ·65 m., the ulna ·33 m., and the femur ·46 m. The total length is about 11 feet 4 inches, and the spread of the massive forearms 16 or 20 feet, this being the most striking feature of the animal. The skeleton was found embedded at the side of a small ravine near the South Fork of the Cheyenne River.—A method for the separation of aluminium from iron, by F. A. Gooch and F. S. Havens. The method is based upon the different solubilities of aluminium and ferric chlorides in strong hydrochloric acid. To test the method, measured portions of the standardised solution of aluminium chloride were evaporated nearly to dryness in a platinum dish, a measured amount of ferric chloride was added in a very little water, a mixture of equal proportions of ether and strong hydrochloric acid was introduced, the liquid was saturated at 15° with gaseous hydrochloric acid, more ether was added to secure complete miscibility, and more gas passed to perfect saturation. The aluminium chloride was collected upon asbestos in a perforated crucible, washed with a mixture of ether and aqueous HCl thoroughly saturated with the gaseous acid, dried at 150° C. for half an hour, covered with pure mercuric oxide, and ignited, gently at first, and finally over the blast. The error was less than 1 per cent.—Chemical composition of Hawaiian soils and of the rocks from which they have been derived, by A. B. Lyons. The relation in chemical composition of soils to the rocks from which they are derived can be most advantageously studied in a volcanic country, where disintegration of the rock is rapid and is attended with great chemical changes. In the Hawaiian soil there is observed a loss of more than half the silica, 77 per cent. of the manganese, 93 per cent. of the lime, 91 per cent. of the magnesia, and about 50 per cent. of the phosphoric acid. It is especially interesting to note that while the rotted lava has lost nearly all its calcium and potassium, the soil retains a considerable proportion of both these elements, probably owing to the influence of plants and molluscous animals.—The Jurassic formation on the Atlantic coast, by O. C. Marsh. Adduces reasons why certain fresh-water formations in New Jersey and elsewhere along the Altantic coast should be regarded as Jurassic instead of Cretaceous.

Bulletin of the American Mathematical Society, vol. iii. No. 2, November.—The number opens with a report of the Buffalo Colloquium, a meeting which was held as auxiliary to the summer meeting of the Society. It lasted a week, and the plan of it was that two courses of lectures should be given, consisting in each case of six one to two-hour lectures. Prof. Bôcher's subject was linear differential equations and their applications, and Prof. Pierpont's the Galois theory of equations. Outlines of the lectures are given. The result was so satisfactory that at the close of the Colloquium a motion was adopted recommending to the Council that arrangements be made for a similar gathering in connection with the next summer meeting of the Society.—A geometrical method for the treatment of uniform convergence and certain double limits, by Prof. Osgood, was read, as previously noted, at the summer meeting. It is a very thorough paper and fully illustrated. The geometrical representation of functions by curves and surfaces is, the author states, of twofold importance; for not only does it represent to the eye, by means of a concrete picture, relations which would otherwise appear only in abstract arithmetic form, but this picture in its turn makes evident new facts, and points out at the same time the curve that the arithmetic proof of the theories thus suggested would naturally take.—Prof. Bôcher reviews Heffter's einleitung in die Theorie der linearen Differentialgleichungen mit einer unabhängigen variabeln.—From the notes we learn that Profs. Klein and J. J. Thomson addressed the Society on October 17.

Symons's Monthly Meteorological Magazine, December.—Weather in the last century. Early records of the weather being somewhat rare, it was thought that summaries of the one in question were worthy of publication. The register was kept at Richmond by Mr. George Smith, a Proctor to Queen Anne, and contains a record of daily observations, made without instruments, from April 1713 to June 1745. The original document is preserved in the library of the Royal Meteorological Society.—The scientific use of kites, by W. L. Moore, Chief of the U.S. Weather Bureau. The question discussed is simply, why kites are better than captive or unmanned balloons for exploring the upper air. The advantages over captive balloons are manifest. Prof. Moore has made out a strong case in favour of kites, but thinks that balloon observations should not be neglected.—*Barometri descriptio*, by J. Addison, 1672–1719. Attention has been called by Mr. Inwards, late President of the Royal Meteorological Society, to a poem under this title which is contained in *Tickell's Addison*, vol. vi. p. 427. The poem is reprinted in the current number of the *Magazine*, and the editor would be glad of a reference to any good translation that may exist.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 10.—"The Chemical and Physiological Reactions of certain Synthesised Proteid-like Substances. Preliminary Communication." By Dr. John W. Pickering.

From the observations recorded in this paper it appears that if certain derivatives of proteids, and other substances of allied chemical constitution, are heated together in sealed tubes with an excess of either phosphorus pentachloride or pentoxide, a series of colloidal substances are formed which, when freed from the contaminating phosphoric acid, and dissolved in concentrated ammonia, give opalescent solutions that, on evaporation down *in vacuo*, yield substances closely resembling in physical, chemical, and physiological properties certain proteids.

These colloidal substances, although they differ from one another in minor details, are usually distinguished by the following characteristics:—

(1) They are soluble in warm water, forming opalescent lævorotatory solutions.

(2) The resulting solutions yield the principal colour reactions hitherto deemed diagnostic of proteids.

(3) In the absence of salts, solutions of these colloids do not coagulate on heating. In the presence of a trace of a neutral salt they coagulate on heating at temperatures very similar to proteid solutions.

(4) Fractional heat coagulation shows the colloidal solutions are a mixture of different substances.

(5) The different constituents of the colloidal solution exhibit different physiological action.

(6) In the presence of an excess of neutral salts, or of salts of the heavy metals, the colloidal solutions behave in a manner similar to proteid solutions.

(7) When introduced into the circulation of pigmented

rabbits, dogs, and cats, certain of these substances (viz. the colloids designated A, B, C, α and β) produce intravascular coagulation of the blood in a manner similar to a nucleo-proteid. They also hasten the coagulability of the blood withdrawn from the carotid, and will, when slowly injected intravenously in minute quantities into dogs, produce a retardation of the coagulability of the intravascular blood, *e.g.* a "negative phase."

(8) Apparently these colloidal substances are owing to both their physical and chemical properties and their physiological behaviour, the nearest synthesised bodies at present known to proteids.

"An Attempt to determine the Adiabatic Relations of Ethyl Oxide." By Dr. E. P. Perman, Prof. W. Ramsay, F.R.S., and J. Rose-Innes, M.A., B.Sc.

Geological Society, December 2.—Dr. Henry Hicks, F.R.S., President, in the chair.—The Secretary announced that Mr. Frank Owen had presented to the Society a photographic portrait of his late grandfather, Sir Richard Owen.—Another possible cause of the glacial epoch, by Prof. Edward Hull, F.R.S. In the introductory portion of the paper the author gave an account of the submarine topography of the area east of North America, and summarised Dr. J. W. Spencer's work upon a submerged Antillean continent; he then dealt with the effects which would be produced upon the Gulf Stream by the uprising of this continent in the glacial period, and maintains that, as the current could not pass into the Gulf of Mexico (being debarred by a coast of high continental land), it would flow directly northwards into the North Atlantic, and thereby be deprived of about 10° (Fahr.) of heat: the effects of which may be practically illustrated by supposing the isothermal line of 32° to take the place of that of 42° in the northern hemisphere. He argued that the increased snowfall which would thus be caused over certain areas would tend to intensify the cold through all the adjoining tracts. To the effects produced in this way must be added those due to the elevation of the land of Eastern North America and to an elevation of North-western Europe, which was supposed to have occurred at the end of Pliocene times. These elevations would intensify the glaciation caused by the difference of direction taken by the Gulf Stream. In the discussion which followed, the Rev. Edwin Hill inquired what were the grounds for the estimated reduction of temperature, and asked for a comparison between the Gulf Stream in such conditions and the present North Pacific current. Dr. Blanford agreed with him in feeling doubtful whether a change in the configuration of the American coast would prevent a warm current from still impinging upon the shores of North-western Europe, and expressed the opinion that the main cause of the glacial epoch was still unknown.—On the affinities of the Echinothuridæ, and on *Pedinothuria* and *Elikodiadema*, two new subgenera of Echinoidea, by Dr. J. W. Gregory. The author summarised and discussed the literature bearing upon the Echinothuridæ, and brought forward arguments to prove that the family is a member of the order Diademoidea, and is derived from the Pedinidæ, members of which are found in earlier rocks than the Corallian, which contains the oldest member of the Echinothuridæ, namely, *Pelanechinus*. He maintained that the extreme flexibility and loose articulation of the plates of the living genera *Asthenosoma* and *Phormosoma* was due to the diminished calcification of the plates, and that these recent genera were extremely specialised forms, and not primitive—the apparently primitive features of the family being secondarily acquired, not primæval.—On *Echinocystis* and *Palæodiscus*, two Silurian genera of Echinoidea, by Dr. J. W. Gregory. The author gave a history of the genera *Echinocystis*, Salter, and *Palæodiscus*, Wyv. Thoms., redescribed their structures, and discussed their affinities. He concluded that *Echinocystis* was an echinid and not a cystid; and that *Palæodiscus* was an echinid and not an asterid.

Linnean Society, December 3.—Mr. C. B. Clarke, F.R.S., Vice-President, in the chair.—Mr. R. Morton Middleton exhibited and made remarks on specimens of *Acer dasycarpum* strangulated by *Aristolochia tomentosa*. He also exhibited examples of *Helix Cumberlandiana*, an extremely local land mollusc from the carboniferous limestone of Tennessee, his remarks being confirmed by Mr. W. Stearn, an American conchologist, who was present as a visitor.—Mr. E. M. Holmes exhibited specimens of *Liebmannia major*, a seaweed not hitherto detected in Britain, and, so far as is known, recorded only from Finisterre. The specimens were collected at Lossiemouth in August 1896. He also showed *Bonnemaisonia hamifera*, collected in May last by Mr. E. George, and in August last by himself. In 1895 living specimens of this seaweed, a native of Japan, were found at Falmouth by the late Mr. T. H. Buffham, and during the present year other examples had been found at Shanklin, Isle of Wight, showing that the plant had apparently become naturalised. The Rev. George Henslow gave the substance of a paper entitled, "Does Natural Selection play any part in the origin of Species among Plants?" After defining a species from the systematists' point of view, the author showed, by examples, that many specific characters in plants might be useful, indifferent, useless or injurious; and that they were the direct result of a responsive action especially to the physical environment. The *origination* of varietal characters, he thought, should be considered as quite distinct from "the survival of the fittest" and "the struggle for life" which determine the *distribution* of species in time and space. The individual differences of plants were held to be (as a rule) inadequate to produce variations of any systematic value, unless the plant migrated, and dimensions *per se* could have no "destructive" capacities whatever. Darwin's and Wallace's conditions for natural selection, viz. large populations and infertility between parents and offspring, had, he considered, no connection with the origination of variations, while the latter did not exist. On the contrary, species with large populations were (as a rule) invariable, while others might vary greatly, but only when in different soils, &c. Instead of "changed conditions of life" happening to any plant without migration, it was the latter which brought them about; instead of a struggle being required with the parent stock or other plants, it was the avoidance of the deteriorating effects of struggling which was most beneficial, and new varieties arise best when there was no struggle at all.

Anthropological Institute, December 8.—Mr. E. W. Brabrook, President, in the chair.—Prof. E. B. Tylor read a paper by Mr. Horatio Hale on four historical Huron wampum-belts, which he exhibited, adding remarks of his own on the employment of wampum in a mnemonic system. After a short account of the state of the Indian confederacies at the time of the arrival of the earliest discoverers, in the course of which the mention of the chief Hiawatha caused Prof. Tylor to contrast the accuracy of Fenimore Cooper as a painter of Indian life with the poetical license of Longfellow, attention was directed to the use of wampum as currency, and to the laborious method of drilling the hard shell to form the beads. Specimens of the two shells employed in the manufacture were exhibited. Dr. Tylor then passed to the symbolic use of wampum-belts as historical records, illustrating his remarks by a number of lantern slides. From these it was explained how the Iroquois belt might be distinguished from others by the occurrence of diagonal bands of beads, contrasting in colour with those forming the ground. These bands are derived from the diagonal rafters of the peculiar "long-houses" of the Iroquois. Other well-known conventional symbols, representing hearts, houses, lands, the "peace path," &c., were also illustrated. One of the belts exhibited was itself an historical record of some interest to Europeans, as it depicts a proposal of conversion to Christianity made by the early Jesuit missionaries to the Indians, the message being effected by working into a wampum-belt a symbolic group consisting of the lamb, the dove, and several crosses. The investigations made by Mr. Hale seem to show that the "Penn Belt," which is now in New England, is not a record of the famous scene depicted by Benjamin West, but of a more obscure treaty concluded with Iroquois chiefs. The intrinsic evidence afforded by the belt convinces Mr. Hale that it was made by Iroquois. In this way anthropology has been able to correct history. Dr. Tylor exhibited lantern slides of West's picture, and of one of Lafitau's plates, the latter giving a far more accurate idea of the ceremonious ratification of an Indian treaty than the former. He also exhibited a slide illustrating the use of wampum-belts as records in modern times, exemplified by the annual meeting of chiefs, at which all the belts are carefully gone over, in order that events of tribal importance may be kept green. A short discussion followed.

Mathematical Society, December 10.—Prof. Elliott, F.R.S., President, in the chair.—Major MacMahon, R.A., F.R.S., stated a result arrived at in a note by Prof. Sylvester, F.R.S., on a discovery in the theory of denumeration. In connection with this communication the President announced that

Prof. Sylvester had put his "Outline of Lectures on the Partitions of Numbers," which he read at King's College, London, in 1859, and which had never been published, at the disposal of the Council, and that that body had arranged to print them as a companion to the ex-President's valedictory address.—Mr. Burbury, F.R.S., communicated a paper on the stationary motion of a system of equal elastic spheres of finite diameter.—Mr. Hough read a paper on the influence of viscosity on waves and currents.—Mr. Macfarlane Gray gave a description of his multiplying apparatus. Messrs. C. V. Boys, F.R.S., and T. I. Dewar, Prof. Greenhill, F.R.S., and other gentlemen, joined in a discussion of points connected with the subject.—Lieut.-Colonel Cunningham, R.E., gave an account of results arrived at in his paper on the connection of quadratic forms.—The following papers were communicated by their titles, viz. : Concerning the abstract groups of order K ! and ½K ! holoedically isomorphic with the symmetric and the alternating substitution groups on K letters, by Prof. E. H. Moore.—On a series of cotrinodal quartics, by Messrs. H. M. Taylor and W. H. Blythe.—On finite variations, by Mr. E. P. Culverwell.

Zoological Society, December 15.—Lieut.-Colonel H. H. Godwin-Austen, F.R.S., Vice-President, in the chair.—The Secretary read a report on the additions that had been made to the Society's menagerie during the month of November 1896.—Mr. Sclater exhibited two bound volumes of original drawings by Joseph Wolf and Waterhouse Hawkins, belonging to the Knowsley library, which had been kindly lent to him for examination by the Earl of Derby. They represented various animals that had been living in the Knowsley menagerie, 1844-48.—Mr. W. Bateson exhibited and made remarks on some pigeons with very well-marked webs between the toes.—Prof. Newton sent for exhibition the type-specimen of *Heterorhynchus olivaceus* of Lafresnaye, kindly entrusted to him by Prof. Hyatt, Curator of the Museum of the Boston Natural History Society. This extinct species, now referred to *Hemignathus lucidus* of Lichtenstein, was peculiar to Oahu, one of the Sandwich Islands, and the present appeared to be the only full-plumaged male specimen ever seen in this country.—Dr. G. Herbert Fowler read a paper entitled "Contributions to our Knowledge of the Plankton of the Færoe Channel," which contained an account of the first results arrived at from his examination of the marine fauna of this channel during a voyage in it, in July and August last, in H.M.S. *Research* (Captain Moore).—The Secretary read a paper by Mr. Oldfield Thomas, entitled "On the Genera of Rodents, being an attempt to bring up to date the current arrangement of the Order." Taking as a basis Alston's paper on the Rodents, published in 1876, the main object of the present communication was to place in their proper positions the many genera described since that author's times. In regard to the larger groups, Alston arrangement had been followed as far as possible ; but among other things it had been thought better to elevate the subfamily Bathyerginæ into a family, to make two families of the Hystricidæ, one for the Old-World and one for the New-World porcupines, and to give to the subfamilies Geomyinæ and Heterominæ full family rank. All the recent genera of the order were enumerated, to the number of 158, as compared with 100 in Alston's list.—Dr. J. W. Gregory gave a description of *Lysechinus*, a new genus of Plesiocidarids from the Tyrolese Trias.—A second paper by Dr. J. W. Gregory related to the classification of the Palæozoic Ophiurids.—A communication was read from the Rev. O. Pickard Cambridge, F.R.S., containing descriptions of four new or little known spiders (Araneidea) from Ceylon, Borneo, and South America.—A communication from Dr. Robert O. Cunningham related to the occurrence of a pair of supernumerary bones in the skull of a Lemur, and to a peculiarity which he had noted in the skull of a young Orang.—A communication was read from Dr. Alph. Dubois, in which he gave the description of a new African Trogan from Lake Tanganyika, proposed to be named *Hapaloderma rufiventris*.

EDINBURGH.

Royal Society, December 7.—The first ordinary meeting of the Society was held, at which Prof. M'Kendrick gave the opening address. He remarked that the number of ordinary Fellows of the Society was now 513, twenty-five having been elected during the past year. Referring to the jubilee of Lord Kelvin, he said the celebrations were unique in their kind, and marked the climax, though not the end of a great career. It was now fifty years since Lord Kelvin became a member of this Society, and during that time he had contributed seventy-two papers, including his famous memoirs on thermodynamics, on the dissipation of energy, and on vortex motion. Prof. M'Kendrick then read short obituary notices of Fellows who had died during the recess. By request of the Council, he then gave an account of recent investigations of his own. He began with some remarks on the structural and physiological nervous unit. He showed that these units in brain structure—neurons, as they were called—were not, as was at one time believed, linked together. There was contiguity of their fine terminations, but not continuity of structure. He next described how it was possible by an arrangement consisting of a variable resistance transmitter, and an induction coil, to stimulate the sensory nerves of the skin electrically, so that some of the elements in music—rhythm and intensity—might be perceived, and even enjoyed by those who had become deaf. Lastly he exhibited his improved phonographic recorder, by which the curves on the cylinder could be amplified so that the form of each might be studied, and made some remarks on the character of these curves.—Papers by Mr. G. R. M. Murray on the reproduction of some marine diatoms, and by Dr. Thomas Muir on the eliminant of a set of quaternary quadrics, on the resolution of circulants into rational factors, and on the eliminant of $f(x) = 0, f(1/x) = 0$, were held as read.

DUBLIN.

Royal Dublin Society, November 18.—Prof. A. C. Haddon in the chair.—The following papers were presented :—Note on Irish annelids in the Museum of Science and Art, Dublin, by Prof. W. C. M'Intosh ; new species of dragon-flies in the Dublin Science and Art Museum, by Mr. George H. Carpenter ; on Fresnel's wave-surface, and the surfaces relative thereto, by William Booth, Principal of Hoogly College, Bengal (communicated by Mr. Thomas Preston).—Prof. W. J. Sollas, F.R.S., gave an account of a journey in the interior of Fiji, illustrated by numerous photographs.

NEW YORK.

National Academy of Sciences, November 17 and 18.—Prof. Ogden N. Rood read a paper on flicker photometers. He called attention to a paper published by him in the *American Journal of Science* for September 1893, on a photometric method which is independent of colour, illustrating its use by determinations of the luminosity of discs of variously coloured paper. In his communication to the Academy, he described five forms of photometer based on the flicker principle. The idea underlying the action of these instruments is identical with that which obtained in his experiments with coloured discs, viz. the rapid distribution of two illuminated surfaces alternately for each other, the flicker disappearing when the two surfaces had equal brightness. The photometric measurements made with this new style of photometer are quite accurate and independent of colour.—Prof. Edward D. Cope read a paper on the geographical distribution of batrachia and reptilia in the Medicolumbian region.—Prof. A. E. Verrill read a paper on the evolution and phylogeny of the gasteropod molluscs, illustrated by beautiful diagrams. He advances the view that the Ophisthobranch molluscs were evolved from Pteropods, and are a type of higher order than the Prosobranchs, notwithstanding that they are hermaphrodites. Their sexual organs are much more complicated, and the loss or thinness of the shell gives greater scope for the development and arrangement of internal organs than can be attained by the Prosobranchs with their hard shells. The Ophisthobranchs furnish the most conspicuous examples in the animal kingdom of protection by mimicry, having lost their hard shell as a means of protection, though they still retain it in the early stages of life. The adults, however, either mimic seaweeds, on which they live, or sponges, hydroids, or corals, known to be poisonous to fishes, the chief enemies of the molluscs. Some beautiful examples were shown of molluscs, living in the Sargasso Sea, which imitate the seaweed, and even the parasitic life upon it. In the discussion, Prof. Cope maintained the correctness of the old theory that the Prosobranchs were the more advanced and higher.—Prof. Othniel C. Marsh read a paper on the Jurassic formation on the Atlantic coast. This formation has long been supposed to be lacking in America ; but Prof. Marsh found it in 1868, near Lake Como in Wyoming, and has now traced it also on the Atlantic coast.—Prof. Alfred M. Mayer read a paper on the equation of the forces acting in the flotation of discs and rings of metal

on water and on other liquids, giving several formulæ. The surface tension of pure water is sufficient to bear up discs or rings of metal for three days in localities free from dust, but the slightest impurity in water destroys the surface tension; even dipping the finger into it, or pouring vapour of ether upon it. Could the water be kept absolutely free from dust, it seems probable that it would retain its surface tension indefinitely. The surface tension of mercury is about ten times as great as that of water, but it overflows the metal, and is not convenient to experiment with. The kind of metal used in these experiments is quite immaterial.—Prof. Simon Newcomb read two papers, one on the physical causes of the variations of latitude. These causes are accumulation of ice and snow, and the alternate northerly and southerly motion of the earth's atmosphere from and towards the poles for a period of three months in one direction, and three months in the other direction in each year. His second paper was on solar motion as a gauge of stellar distances. He finds that the stars observed have an apparent drift southward of about 2″ a year, indicating that the solar system is moving at that rate in the direction of Alpha Lyræ. His observations show, also, that the stars of smaller magnitudes are not so remote from the earth as their magnitude would indicate, the increase of distance being about one-fifth for each decrease in stellar magnitude. This seems to warrant the inference, he thinks that the visible universe has a definite limit in space.—Prof. C. S. Hastings read a paper on a new type of telescope free from secondary colour. He finds it possible, by proper arrangement of silicate glasses, to eliminate secondary colour entirely, and also to reduce the length of the telescope tube one half, obviously giving a great advantage in the construction of large telescopes where the weight of the object-glasses has to be supported at a great distance from the point of support.—Prof. Ira Remsen read two papers: one on the hydrolysis of acid amides; the other on the isomeric chlorides of paranitro-orthosulphobenzoic acid.—Prof. C. S. Peirce read two papers: one on a graphical method of logic; the other on mathematical infinity.

PARIS.

Academy of Sciences, December 14.—M. A. Cornu in the chair.—On a new form of the equations to the problem of three bodies, by M. H. Poincaré.—On a class of transcendental functions, by M. Emile Picard.—The theory of the confluence of lymphatics and the development of the lymphatic ganglions, by M. L. Ranvier.—The application of the Röntgen rays to pulmonary tuberculosis, by M. C. H. Bouchard. The continuation of the study of one of the cases of pleurisy previously described shewed an opacity at the summit of the lung, appearing to result from a condensation of the pulmonary tissue, and this was confirmed by percussion and auscultation. In all the cases of tuberculosis examined with the aid of the fluorescent screen, the number of pulmonary lesions has been clearly made out, and in all diseases of the thorax the application of this method forms a valuable aid to diagnosis.—On the third scientific campaign of the *Princess Alice*, by S. A. Albert I., Prince of Monaco. This communication is chiefly occupied with the results of deep-sea soundings in the neighbourhood of the Azores, and in the Mediterranean.—A new double image micrometer, particularly suitable for the measurement of small diameters, by M. G. Bigourdan.—On Taylor's series, by M. Emile Borel.—On a linear partial differential equation of the second order, by M. J. Le Roux.—On the quadratic integrals of the equations of dynamics, by M. G. di Pirro.—On the longitudinal tension of the kathode rays, by M. Colard. Starting with the hypotheses that the ray consists of the transport of negatively charged molecules, and that the electric field is negligible in the space considered, the conclusion is drawn that the behaviour of a kathode ray in a magnetic field is similar to that of a perfectly flexible conductor carrying the same current.—On some errors admitted as facts in electromagnetism, by M. Vaschy. In the case of the movement of a magnet under the influence of a current of constant intensity, the usual calculation of their relative energy neglects the heat evolved by the current. Other examples are given of similar cases.—On selenic anhydride, by M. René Metzner. A comparison of the thermochemical data of sulphuric and selenic acids; the formation of selenic anhydride from selenious anhydride and oxygen is an endothermic reaction.—Analysis of copper by the electrolytic method: estimations of arsenic, antimony, sulphur, and foreign metals, by M. A. Hollard. A continuation of a previous paper on the same subject.—On the antimonio-tungstic combinations, by M. L. A. Hallopeau.—Researches on the sulphides of cobalt and nickel, by M. G. Chesneau. The solubility of cobalt sulphide in sodium polysulphide increases rapidly with the excess of sulphur present. The sulphide of cobalt obtained in this way approximated to the composition $CO_2.S_7$. Nickel gives with the same reagent a black polysulphide of perhaps analogous composition, differing from the cobalt salt in being soluble with difficulty in sodium polysulphide, and more soluble in the monosulphide.—New method for the estimation of glycerol, by MM. F. Bordas and Sig. de Raczkowski.—On 1 : 3 di-bromo-propylene, by M. R. Lespieau. This substance ($CHBr : CH.CH_2.Br$) is obtained by the action of phosphoric anhydride upon symmetrical dibromhydrin.—On the decolorisation in wines, by M. J. Laborde. Under the action of the oxydase present in a culture of *Botrytis cinerea*, a wine was completely decolorised in four hours. This oxydase is destroyed by heat, hence the best method of preventing the spontaneous decolorisation of wines is to raise the wine to a temperature sufficiently high to destroy the ferment.—Coagulating and toxic properties of the liver, by MM. Mairet and Vires. By the action of heat upon the extracts a precipitate is formed, possessing coagulating properties; the filtrate contains the toxic principles.—Replacement of the amibocytes and phagocytic organ in the *Paludina vivipara*, by M. L. Cuénot.—On the development of Annelids, by M. Auguste Michel.—Contributions to the study of the *Rouget*, by M. S. Jourdain. The disease known as "rouget," "bête rouge," &c., is due to the attack of an acarus (*Trombidion*), in a larval hexapodal form.—On the formation of non-nitrogenous food stores in the nut and almond, by M. Leclerc du Sablon.—Action of some substances on the germination of the spores of black rot, by MM. L. Ravaz and G. Gouirand.—On an apparatus designed to show that the quantity of dissolved gas in sea-water at great depths is independent of the pressure, by M. Jules Richard. A description, with diagrams, of the apparatus used in the deep-sea soundings on the last voyage of the *Princess Alice*.—On the influence of certain living organisms on the quantities of oxygen and carbonic acid dissolved in sea-water, by M. Marten Knudsen. The observations on the amount of dissolved oxygen in the superficial layers made by Dittmar, in the *Challenger* Expedition, and later by Tornoe, show great variations, the quantities found being in some cases greater than that calculated from the law of solubility of gases. These results were attributed by Dittmar to errors of observations, but similar results having been obtained during the expeditions of the *Ingolf* to Greenland, although by a different method from those adopted by other observers, led to the discovery that this excess was due to the presence of a great number of living copepods.—On a red rain that fell at Bizerte (Tunis), by M. Ginestous. The colouring matter was of a mineral nature, which from its composition would appear to consist of the débris of a granulitic pegmatite.—The cooling of the globe, the primordial cause of evolution, by M. R. Quinton.

NEW SOUTH WALES.

Linnean Society, October 28.—Mr. Henry Deane, President, in the chair.—The President formally announced the death, on the 10th inst., of Baron von Mueller, who was one of the first two honorary members of the Society to be elected (January 22, 1876).—On the motion of Mr. J. H. Maiden it was resolved that (1) the members of this Society desire to express the profound regret with which the tidings of the decease of Baron von Mueller have been received; and at the same time to place on record their high appreciation of the Baron's life-work, which has in so eminent a degree contributed to the advanced state of our knowledge of the flora of Australia. (2) A copy of this resolution be forwarded to the surviving sister of the late Baron, with an expression of the Society's sympathy in her bereavement.—The President read a letter from the Royal Society of Tasmania, offering to co-operate in any movement to raise some appropriate memorial of the late Baron von Mueller.—The following papers were read:—Australian *Termitidæ* (Part ii.), by Walter W. Froggatt. The author discusses the classification of the family, and proposes its subdivision into four subfamilies based upon the characters of the neuration of the wings.—Note on the occurrence of Palæozoic *Radiolaria* in New South Wales, by Prof. David. With the exception of the opal rocks, which contain numerous spherical casts, possibly of

radiolaria, all radiolarian rocks at present known in New South Wales are of Palæozoic age, and occur on two geological horizons, namely, Carboniferous (? or Devonian), as in the red jaspers of Barraba and Bingera, and the claystones and cherts, &c., of Tamworth; and Devonian or Silurian as at Jenolan Caves, in which locality the radiolaria are best preserved where the rocks are in contact with eruptive dykes. The author is led to the conclusion that these radiolarian rocks are not necessarily of deep-sea origin. In Palæozoic times in New South Wales the development of radiolaria both vertical and horizontally was very extensive.—Note on traces of *Radiolaria* in pre-Cambrian rocks near Adelaide, by Prof. David and Walter Howchin. The recent microscopic examination of calcareous and cherty rocks of undoubtedly pre-Cambrian age from South Australia has shown that these rocks, not previously known to be ossiliferous, contain abundant remains of radiolaria.

AMSTERDAM.

Royal Academy of Sciences, October 31.—Prof. van de Sande Bakhuyzen in the chair.—Prof. W. Kapteyn on the construction of a curve of the third order, its real foci, its satellite-point and a tangent being given.—Prof. van der Waals demonstrated that the value of b in the equation of fluids which, when they are in a state of great rarefaction, is equal to four times the molecular volume, decreases with diminishing volume. The formula

$$b = 4m\left\{1 - \epsilon_1\left(\frac{4m}{V}\right) + \epsilon_2\left(\frac{4m}{V}\right)^2 \&c.\right\}$$

represents the variation of b with the volume. Of the coefficients ϵ_1, ϵ_2, &c., only the first has been calculated, and has been found equal to $\frac{5}{18}$.—Prof. Weber communicated the conclusions drawn from 254 determinations of the absolute and the relative weight of the brains of mammals. A hippopotamus amphibius of 1755 kilogr. had brains weighing only 582 gr. Consequently the ratio is 1 : 3105. This is the most unfavourable one hitherto fixed by weighing. Only the relative weight of the brains of the large cetacea presents a more unfavourable ratio, which, however, is founded on estimation. In many respects the hippopotamus has preserved the character presented by the brains of the tertiary mammals.—Prof. Franchimont on the fusing point of organic bodies. The speaker drèw attention to the variation of the fusing point taking place when hydrogen atoms are replaced by other elements or groups of atoms, and took it that the latter, though they become united with the same atom, do not occupy the same place, so that a change in the form of the molecule is brought about, which influences the fusing point. This change of form counteracts in some cases the effect of the increase of the molecular weight, which consists in a rise of the melting point, and seems to be brought about principally by the CH_3 group, which, when in contact with oxygen, nitrogen, or carbon, can cause the fusing point to fall. To such a change of form the speaker also wished to ascribe the phenomenon observed by himself and Zincke in 1872, viz. a variation of the fusing point in terms of an homologous series with an even and an odd number of C atoms alternately. The speaker had met with this phenomenon in other cases also.—Prof. Engelmann treated of myogenic self-regulation of the action of the heart, and presented a paper on the subject for publication in the Academy's *Proceedings*.—Prof. Lorentz presented a paper to be published in the Academy's *Proceedings*, entitled "a universal theorem concerning the motion of a viscous fluid with friction, and a few consequences deduced from it."—Prof. Kamerlingh Onnes communicated two papers: (*a*) by Dr. Zeeman, on the influence of a magnetisation on the nature of the light emitted by a substance. Pursuing a hint given by Faraday, several experiments were tried. The principal was this: the light of the electric arc, being sent through a heated tube containing sodium vapour, is analysed by a Rowland's grating. The tube is placed between the poles of an electro-magnet. When acted on by the magnet, a slight broadening of the two sodium lines is seen, tending to show that forced vibrations are produced in the atoms by the action of magnetism; (*b*) by Dr. J. Verschaffelt, on capillary ascent between two concentric cylindrical tubes, being measurements carried out in the Leyden Physical Laboratory. In a previous communication Mr. Verschaffelt, to calculate the capillary ascent of liquid carbonic acid, made use of an hypothesis, viz. that the meridian section of the surface of the liquid was an ellipse. The writer has put this manner of calculation to the test of observation. For this purpose, however, he has not used liquid carbonic acid, but methyl chloride, and has found a satisfactory correspondence to exist between the value deduced from observation and that arrived at by calculation.—Mr. Jan de Vries presented, on behalf of Prof. L. Gegenbauer, of Vienna, a paper entitled "Zwei allgemeine Sätze über Sturm'sche Ketten."

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (mathematico-physical section, Part 3) contains the following memoirs recently communicated to the Society.

August 1.—Charles A. Noble (San Francisco): Solution of the boundary equation for a plane contour composed of segments of continuous curvature and without salient angles. R. Fricke (Brunswick): On a simple group of 360 operations. W. Voigt: An attempt to determine the true specific electric moment of a tourmaline.

October 24.—J. Orth: (1) On the formation of fibrin on serous and mucous membranes; (2) Researches conducted in the Göttingen Pathological Institute. W. Voigt: (1) A new method of investigating the thermal conductivity of crystals; (2) On the position of the absorption-brushes in biaxial pleochroic crystals. The formal communications (Part 2) include the address voted to Lord Kelvin upon his recent jubilee, and that to Prof. Wilhelm Hittorf, of Münster, on his *doctorjubiläum*.

THURSDAY, DECEMBER 31, 1896.

ANCIENT ASTRONOMY IN INDIA.

Hindu Astronomy. By W. Brennand. Pp. xiv + 329. (London: Chas. Straker and Sons, Ltd., 1896.)

THE ancient mathematical and astronomical works of the Hindus are worthy of more attention than they have yet received from Europeans. A lengthened residence in India led Mr. Brennand to become interested in the study of some of these, which was frequently interrupted by the pressure of official duties; but after his retirement he took up the subject again, and presented a paper on it to the Royal Society about five years ago. The interest manifested in this has encouraged him in the composition of the work before us, which it is hoped will have the effect of making the Hindu system of astronomy more generally known, and perhaps induce others to make further investigations on the subject. He begins by a discussion of the ancient zodiac, and its general correspondence amongst the Indians, Chinese, Chaldæans, Arabians, and Egyptians; treats also of the other division of the ecliptic into so-called lunar mansions; and shows the bearing of this upon the probability that the Hindus had originally migrated from Central Asia into India. This, however, is a view which probably few at the present time would dispute, as that is understood to be the original home of the Aryan race. It is when we come to the astronomical calculations with regard to the movements of the planets, the precession of the equinoxes, and the prediction of eclipses, that the problem of the source and origin of the astronomy contained in the Hindu books stands before us. Now as to the precession of the equinoxes, H. T. Colebrooke (who afterwards became the second President of the Astronomical Society, succeeding Sir William Herschel) pointed out in 1816 ("Asiatick Researches," vol. xii. p. 221), that the Hindus "had approximated to the true rate of that motion much nearer than Ptolemy, before the Arabian astronomers, and as near the truth as these have ever done since." The Hindus, indeed, appear to have reckoned it at one and a half degrees in a century, which is equivalent to a revolution in 24,000 years; whereas Albatenius, the earliest of the Arabian astronomers who improved upon Ptolemy, made it a degree in 66 years, which amounts to a revolution in 23,760 years. The true value of this is about 25,800 years; but though the Hindu is nearer it than the Arabian, the difference is hardly enough to warrant us in concluding that the two are independent.

Mr. Brennand's second chapter is on "Early Hindu Periods." A day of Brahma was called a Kalpa, and was supposed to comprise a period of no less than 4,320,000,000 years. A thousandth part of this was a Maha-Yuga, and a tenth of a Maha-Yuga was a Kali-Yuga, or 432,000 years. At the beginning of each Kali-Yuga the sun and all the planets were supposed to be in conjunction, and the beginning of the present Kali-Yuga corresponded to B.C. 3102 of our era. But, as Laplace pointed out in the "Exposition du Système du Monde," the conjunction was not near enough to permit us to suppose that the epoch in question was founded on observation; it must have been "invented for the purpose of giving a common origin to all the motions of the heavenly bodies in the zodiac." With regard to the enormous periods of time which the vanity of other nations besides the Hindus led them to claim, it does not seem to us that Mr. Brennand is particularly successful in endeavouring to explain it by taking a year as in fact a month, or season, and so reducing the period. Not to refer again to the Hindu Kalpa, many other periods, even reduced in this way, are absurdly long. Mention is here made of the list of eclipses said to have been sent to Aristotle by Callisthenes from Babylon, extending over a period of nineteen centuries before his time. The sole authority for this is Simplicius, who himself believed that the record sent never reached its destination, as no work then extant of Aristotle referred to it, and, as Delambre remarks, the whole thing is probably a fable.

Our author proceeds to give a very elaborate and interesting account of the Hindu mathematics and methods of astronomical calculation. Colebrooke, in the article which we have already quoted, rightly remarks that these are interesting, not in a scientific (no observations being given that can be verified), but in an historical point of view. History, however, requires chronology as her handmaid; and the date of the beginning of Hindu astronomy seems very difficult to determine with even approximate accuracy. Mr. Brennand's view is that it is really very ancient, but that it suffered an eclipse during the rise of Buddhism, and was afterwards revived. Now this took place about five centuries before the Christian era, but Buddhism first became recognised as a State religion under Asoka about the middle of the third century before Christ. During its rise amongst the people, it is thought that there was a great destruction of manuscripts, and, as Mr. Brennand points out, we are sometimes rather apt to forget how difficult it would be, without the aid of printing, to keep intact scientific knowledge which had been acquired. One of the great revivers of astronomy amongst the Brahmins was a mathematician named Aryabhatta, who is supposed to have lived not long before the time of the Christian era. He taught the diurnal rotation of the earth, and explained the true cause of solar and lunar eclipses; he is said also to have noticed the motion of the equinoctial points, but to have restricted it to a periodical oscillation. It is suggested that the allegory of the death of Durga (which, in the nature of its symbolism, reminds us of the weeping for Tammuz, which the Israelites adopted from the Babylonians, as Ezekiel was horrified to see it practised by them) was invented by the Brahmins to represent and keep in memory the decline of their favourite science, afterwards revived. We must now pass on to the age of Brahmagupta, which was probably about six centuries after Christ, or nearly the time of Mohammed. As compared with Aryabhatta, his teaching appears to have been in some respects retrograde, but his principal work was a revised and corrected edition of the ancient sacred work, "The Brahma Siddhanta," from some earlier copy which had been preserved.

The word "Siddhanta", it may be remarked, signifies "established conclusion," and a number of astronomical treatises exist under this title, though their exact date

in their original shape, cannot be determined. Brahmagupta's edition of the above was called "The Brahma Sphuta Siddhanta," "Sphuta" meaning "amended" or "corrected" (perhaps "restored" would be better). Colebrooke translated two chapters of this from the Sanskrit. They are chiefly mathematical, giving methods for performing trigonometrical, geometrical, and algebraical questions. It should be mentioned that the four principal Siddhantas are reputed by the Hindus to have been inspired; the Brahma Siddhanta having been, they say, revealed by Brahma, the Surya Siddhanta by the sun, the Soma Siddhanta by the moon, and the Brihaspati Siddhanta by Jupiter. Mr. Brennand gives a very particular description of the Surya (or sun) Siddhanta, but we can mention only a few points to which he calls attention. The ancient cycle of sixty years, common to the Chaldæans, the Chinese, and the Hindus, consisted, in fact, of five periods of the planet Jupiter round the sun. As regards the planetary motions, they were all supposed to be of uniform velocity in themselves, though some appeared to move more slowly than others, on account of their greater distances. The Brahmins approximated very closely to the true length of a year. Mr. Brennand devotes a very considerable space to a description of their methods of astronomical calculation, which are worthy of careful study; but we must now conclude this short sketch of his interesting work by reiterating his own hope that his book may lead to further investigations on the subject.

W. T. LYNN.

AMBER IN SCIENCE AND THE ARTS.

The Tears of the Heliades; or, Amber as a Gem. By W. Arnold Buffam. Pp. 98, 8vo; with illustrations. (London: Sampson Low, Marston, and Co., Ltd., 1896.)

THAT the classical account of the origin of amber has not been sufficiently practical to satisfy modern inquirers, is proved by the interest that has always been attached to the subject, and more especially in recent years. The wide geographical range over which this fossil resin is now found, and the different conditions of the several deposits, has increased the interest and speculation with regard to the number and character of the trees or plants from which the resin exuded in long past ages; but speculation has of late been largely converted into fact by the systematic study of a mass of material that has been carefully examined by Dr. H. R. Goeppert and A. Menge, and more recently by Dr. H. Conwentz.

Goeppert and Menge's "Die Flora des Bernsteins," published at Dantzig in 1883, is, moreover, illustrated by a number of splendidly executed coloured plates, showing not only lumps of amber of different formation, but also sufficient material of wood structure to prove certain botanical affinities, and of floral and leaf-forms found in masses of the fossil resin.

In Dr. H. Conwentz's contribution to this subject, published at Dantzig in 1886, the plants referred to are arranged in their natural orders, commencing with the monocotyledons. This is also illustrated by a fine series of plates. Dr. Conwentz further published—at Dantzig in 1890—a "Monographie der Baltischen Bernsteinbäume," and at the Ipswich meeting of the British Association in 1895 gave a very valuable address "On English amber and amber generally," and as this paper was printed in *Natural Science* (vol. ix. Nos. 54 and 55, for August and September last), it may certainly be regarded as the best contribution in the English language to this interesting subject.

Though Mr. Buffam in his "Tears of the Heliades" devotes one chapter of twenty-four pages to the consideration of the plants furnishing amber, and their geographical distribution, he does not seem to have been acquainted with Dr. Conwentz's researches. The two authors, however, have been working on different lines. Dr. Conwentz in his paper has paid special attention to English amber and to the sources of amber particularly, while Mr. Buffam has treated his subject, as one of his titles indicates, from an artistic point of view, and in this we must say he has succeeded in making a most charming book. His description of the Sicilian amber shows at once that his admiration of the gem amounts to enthusiasm, and in this the reader is almost carried away with the same enthusiasm with such paragraphs as the following description of a gold and amber necklace which he saw on the neck of an Italian girl.

"Whilst she spoke," he says, "the gems in her necklace flashed in the sunlight, showing colour shades ranging from faint blue to deepest azure, and from pale rose to intense pigeon-blood, ruby red. The varied and lustrous hues here blended in lavish beauty drew from me involuntary expressions of admiration."

The beauty of these gems is further impressed on the reader's admiration by an excellent reproduction in colours and gold, forming the frontispiece to the book; gems such as these, however, it is stated are rare even in Sicily. Sicilian amber, we are told—

"is only found on or near the surface of the ground in an accidental manner, scattered over a wide extent of country, having been transported by down-pouring rains and by brooks and rivers far from its primary bed, which is believed to be in the neighbourhood of the Central Mountains, where Gemmellaro and Maravigna, in fact, affirmed its existence."

It is not necessary to dilate here on the general uses of amber, such as for mouthpieces of pipes, beads, brooches, &c., as this has been exhaustively treated of by nearly all writers on the subject; but the bulk of the amber of commerce is the yellow kind obtained in such large quantities from the Baltic. It may, however, be as well to refer to its early use in medicine, and on this head Mr. Buffam says:—

"The ancients employed amber as a medicine, and it is still prescribed by physicians in France, Germany and Italy, and several chemists in Paris keep it constantly in stock. It has been worn by ladies and children from time immemorial as an amulet, sometimes carved into amphoræ, and has been pronounced of service either taken internally or worn round the neck."

It is remarkable that the resin should still be used on the continent as a medicine, as stated by Mr. Buffam, for though it formerly had a reputation as a stimulant and antispasmodic in England, it has been discarded by us for at least forty or fifty years as possessing no medicinal properties.

As a material for varnish making, amber was a recognised commercial article in the sixteenth century. Whether it was the basis of the varnish used by the old violin makers has long been a disputed question, which can never be satisfactorily settled. It is not improbable that the peculiar electric qualities possessed by amber may have exercised some influence in producing the marvellous tones of the violins of the old masters; and the extremely dangerous and difficult task of melting amber in either fixed or volatile oils, on account of its liability to fire under heat, would preclude any attempt at its manufacture except in the laboratory and under personal superintendence, so that the secret of its preparation died with each master.

On the other hand, the danger and difficulty attending the melting of the substance has been advanced as a reason against the probability of its use. As a modern varnish material, amber is now scarcely in demand. With regard to English amber, though specimens are not unfrequently found on the Norfolk, Suffolk, and Essex coasts, as stated by Dr. Conwentz, there has been some doubt as to the genuine character of some of the pieces, which appear to have been copal or anime rather than true amber. The similarity in the formation of the two resins is borne out by an illustration of concentric structure given by Dr. Conwentz in his valuable paper before alluded to, with a specimen of Demerara copal from the locust tree (*Hymenæa Courbaril*) in the Kew Museum.

JOHN R. JACKSON.

THE RED DEER.

Fur and Feather Series: Red Deer. Natural History, by Rev. H. A. Macpherson; *Stalking*, by Cameron of Lochiel; *Hunting*, by Viscount Ebrington; *Cookery*, by A. I. Shand. Pp. viii + 320. 12mo, illustrated. (London: Longmans, Green, and Co., 1896.)

ALL contributions to the natural history of the finest of our British mammals cannot fail to be interesting to all with a zoological turn of mind; while accounts of the stalking and chase of the same noble animal will command attention from a still wider circle of readers. Whether the three chapters which Mr. Macpherson contributes to the little work before us form an adequate account of the natural history of *Cervus elaphus*, may be a moot point, but to our mind they are too "parochial." There is, for instance, nothing said as to the distribution of the red deer, or its relations to other members of the same genus; and the chief attention is directed to its breeding-habits. The author of these chapters appears to derive most of his knowledge of the animal from the Lake District; and the first chapter is nothing more than a description and history of the fells of Westmoreland, with some casual observations on red deer thrown in. It is written in a pleasant and gossipy style, but as its purport has already appeared in the pages of "Lakeland," its reproduction here seems superfluous. The third chapter in the natural history section is entitled "Echoes of the Chase," and would more appropriately have come in Lord Ebrington's section.

Indeed, the work decidedly suffers from insufficient editing. For instance, most of Lord Ebrington's very interesting remarks on antlers, in the chapter entitled "Deer," should clearly find a place in the natural history portion. Again, after Mr. Macpherson had written, on page 34, that "Deer, by the way, are very fond of nibbling the remains of shed antlers," the editor ought not to have permitted the following sentence, by Lord Ebrington, to appear on page 278.

"I have never heard any explanation that accounted for this [the rarity of the discovery of the bodies of dead deer] satisfactorily, for the hinds would not eat carrion, though there seems little doubt that they will eat both bones and shed horns."

Either the matter is, or is not, a certainty, and one allusion would suffice.

So far as we are capable of judging, the chapters on stalking and hunting form admirable and interesting accounts of these sports. In addition to the remarks on antlers already mentioned, Lord Ebrington gives us many interesting observations which might well find a place in works on natural history. In reference to the "gait" and "slot," he writes that—

"A stag's dew-claws point outward, and are large in proportion to his own size, while a hind's are small, turn inward, and point straight down. A stag crosses his legs right and left in walking, while with a hind the prints of the hind foot will be in a direct line with those of the fore foot, unless she is heavy in calf. . . . The extra weight on the legs is no doubt the reason, and at calving time the stags are defenceless too, having shed their horns. The stag moves with more confidence than the hind, so his paces are regular. The hind moves femininely and distrustfully; sometimes she will put her hind feet down in front of the spot from where she has just lifted her fore ones, sometimes on the same spot, sometimes behind it."

Unless we are greatly mistaken, there are few professed naturalists who could have given such details; and yet they are surely of much more interest than the endless multiplication of species.

The illustrations are charming works of art, and the volume must claim a place in the library of every sportsman, if not of the naturalist also.

R. L.

OUR BOOK SHELF.

The Tutorial Chemistry. Part I. *Non-Metals.* By G. H. Bailey, D.Sc., Ph.D. Pp. viii + 226. (London: W. B. Clive, 1896.)

Elementary Non-Metallic Chemistry. By S. R. Trotman, M.A. Pp. viii + 183. (London: Rivington, Percival, and Co., 1896.)

IF the publication of text-books is a sign of increased attention to the branches of science with which they deal, chemistry must be making great progress; for no week, and scarcely a day, passes without the receipt of a manual for chemical students. The two volumes now before us are fair representatives of a class of text-books designed to furnish boys with the facts which examiners periodically endeavour to entice from them.

Dr. Bailey's book furnishes a systematic outline of chemistry, so far as it relates to the non-metals. Acting upon the conviction that a knowledge of physical principles and measures should be gained from an elementary text-book of physics, Dr. Bailey has omitted the preliminary chapters usually devoted to these matters, notwithstanding the growth of opinion that experiments and measurements of physical properties of matter form the best basis for a chemical education. He does not, however, ignore the physics of chemistry altogether, for a chapter is devoted to the physical properties of gases.

The fundamental principles of chemistry, and the nature of chemical action, are laid down in the first twenty pages of the book, after which the non-metals and some of their common compounds are described. As a companion in the laboratory, containing details of many instructive experiments, the book should find favour.

On page 8 we read: "Quite recently it has been found that Helium, one of the bodies which had already been observed in the corona of the sun, occurs in the gases extracted from certain minerals by heating them in vacuo." Helium is a constituent of the solar prominences, but not of the corona.

Mr. Trotman's book follows very much the same lines as that of Dr. Bailey; but it is more suitable for use in connection with elementary classes than for the laboratory. It is an attractive little volume, simply worded, clearly printed, and plainly illustrated. We regret to notice the absence of an index.

Hygiene for Beginners. By Ernest S. Reynolds, M.D. Pp. xiv + 235. (London: Macmillan and Co., Ltd., 1896.)

THERE are a number of good elementary books on hygiene, but this one will find a place among the best of them. The author's "Primer of Hygiene" is very well known, being widely used in Evening Continuation Schools, Technical Institutes, and County Council courses. A knowledge of elementary anatomy and physiology is, however, essential before the main principles of hygiene can be intelligently grasped. Recognising this, the author has introduced chapters on the structures and functions of the various parts of the human body, and has considerably enlarged his "Primer" in other directions. The first hundred pages of the present volume comprise nine chapters on elementary anatomy and physiology; the remaining nine chapters are devoted to that extensive and varied knowledge concerned in the prevention of disease. The book is thus thoroughly in touch with the syllabus of elementary hygiene of the Department of Science and Art. We are not given to praising books moulded to particular syllabuses, but the present volume does not slavishly follow the lines laid down by the examiner in the subject with which it deals, and the independence is a sign of the author's ability to judge for himself the best arrangement and scope of the matter. It would be to the advantage of the community if every individual had to pass an examination in the subjects dealt with; and we venture to say that every householder, and every mother having the care of children, should be acquainted with as much of the elementary principles of hygiene as is contained in this volume. As to teachers of South Kensington classes in hygiene, they only need to see the book to appreciate its admirable qualities.

The Parasitic Diseases of Poultry. By Fred. V. Theobald, M.A., F.E.S. Pp. xv + 120. (London: Gurney and Jackson, 1896.)

POULTRY are subject to many parasitic diseases, and the object of this manual is to inform poultry-keepers of the life-histories of these pests, so that means of prevention may be successfully carried out. Mr. Theobald is zoologist to the Agricultural College at Wye, while his knowledge of the characteristics and habits of the parasites he describes has been gained from observation of many diseased birds. Poultry-breeders and fanciers may, therefore, safely trust themselves to be guided by him; and they will learn from his book how to distinguish and cope with the animal and vegetable parasites which often cause them such serious loss. Entomologists will discover in the work some new points on the life-histories of the parasitic forms dealt with, as well as a list of the parasites found upon fowls.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Letters of Charles Darwin.

I AM preparing to publish a supplementary series of Charles Darwin's letters. My projected volume will include a full selection from those letters of a purely scientific interest which I was unable to print in the "Life and Letters," as well as from any fresh material that may now be entrusted to me.

I would, therefore, ask those of my father's correspondents who have not already done so to allow me to make copies of any letters of his which they possess. I venture to remind those who may be inclined to help me, that letters of apparently slight or restricted interest are often of value. FRANCIS DARWIN.

Wychfield, Cambridge, December 26.

On the Goldbach-Euler Theorem regarding Prime Numbers.

IN the published correspondence of Euler there is a note from him to Goldbach, or, the other way, from Goldbach to Euler, in which a very wonderful theorem is stated which has never been proved by Euler or any one else, which I hope I may be able to do by an entirely improved method that I have applied with perfect success to the problem of partitions and to the more general problem of demonstration, *i.e.* to determine the number of solutions in positive integers of any number of linear equations with any number of variables. In applying this method I saw that the possibility of its success depended on the theorem named being true in a stricter sense than that used by its authors, of whom Euler verified but without proving the theorem by innumerable examples. As given by him, the theorem is this: *every even number* may be broken up in one or more ways into two primes.

My stricter theorem consists in adding the words "where, if $2n$ is the given number, one of the primes will be greater than $\frac{n}{2}$, and the other less than $\frac{3n}{2}$. This theorem I have verified by innumerable examples. Such primes as these may be called mid-primes, and the other integers between 1 and $2n-1$ extreme primes in regard to the range $1, 2, 3 \ldots, 2n-1$.

I have found that with the exception of the number 10, Euler's theorem is true for the resolution of $2n$ into two *extreme* primes; but this I do not propose to consider at present, my theorem being that, with exception of $2n = 2$, every even number $2n$, may be resolved into the sum of two mid-primes of the range $(1, 2, 3 \ldots 2n-1)$. As, *ex. gr.*

4 =	2 +	2	6 = 3 +	3	8 =	5 +	5	10 = 3 + 7
12 =	5 +	7	14 = 7 +	7	16 =	5 +	11	
18 =	5 +	13	7 +	11	20 =	7 +	13	
40 =	11 +	29 =	17 +	23	50 =	13 +	37 =	19 + 31
100 =	29 +	71 =	41 +	59				
200 =	61 +	149 =	73 +	127 =	&c.			
500 =	127 +	373 =	193 +	307 =	&c.			
1000 =	257 +	743 =	&c.					

And so on.

My method of investigation is as follows. I prove that the number of ways of solving the equation $x + y = 2n$, where x and y are two mid-primes to the range $2n-1$, *i.e.* twice the number[1] of ways of breaking up $2n$ into two mid-primes + zero or unity, according as n is a composite or a prime number, is exactly equal to the coefficient of x^{2n} in the series

$$\left(\frac{1}{1-x^p} + \frac{1}{1-x^q} + \ldots + \frac{1}{1-x^l}\right)^2$$

where $p, q, \ldots, l$ are the mid-primes in question. This coefficient, we know *à priori*, is always a positive integer, and therefore if we can show that the coefficient in question is not zero, my theorem is proved, and as a consequence the narrower one of Goldbach and Euler. By means of my general method

[1] This number may be shown to be of the order $\frac{n}{(\log n)^2}$ and a very fair approximate value of it is $\frac{\mu^2}{n}$ where μ is the number of mid-primes corresponding to the frangible number $2n$

of expressing my rational algebraical fraction, say ϕx, as a residue, by taking the distinct roots of the denominator, say ρ, and writing the variable equal to $\rho\epsilon^{\theta}$, and taking the residue with changed sign of $\Sigma\rho^{-n}\epsilon^{-n\theta}\phi\rho\epsilon^{\theta}$, we can find the coefficient of x^n or (if we please to say so) of x^{2n} in the above square, and obtain a superior and inferior limit to the same in terms of $p, q, \ldots, l$; and if, as I *expect* (or rather, I should say, *hope*) may be the case, these two limits do not include zero between them, the theorems (mine, and therefore *ex abundantia* Euler's) will be apodictally established.

The two limits in question will be algebraic functions of $p, q, \ldots, l$, whereas the *absolute* value of the coefficient included within these limits would require a knowledge of the residues of each of these numbers in respect to every other as a modulus, and of $2n$ in respect of each of them. In a word, the limits will be algebraical, but the quantity limited is an algebraical function of the mid-primes $p, q, r, \ldots l$.

J. J. SYLVESTER.

Athenæum Club, December 20.

P.S.—The shortest way of stating my refinement on the Goldbach-Euler theorem is as follows:—"It is always possible to find two primes *differing by less than any given number* whose sum is equal to twice that number."

Another more instructive and slightly more stringent statement of the new theorem is as follows. Any number n being given, it is possible to find two primes whose sum is $2n$, and whose difference is less than n, $n-1$, $n-2$, $n-3$, according as n divided by 4 leaves the remainders 1, 0, -1, -2 respectively.

Major MacMahon, to whom and to the Council of the Mathematical Society of London I owe my renewed interest in this subject, informs me that in a very old paper in the *Philosophical Magazine* I stated that I was in possession of "a subtle method, which I had communicated to Prof. Cayley," of finding the number of solutions in positive integers of any number of linear equations in any number of variables. This method (never printed) must have been in essence identical with that which within the last month I have discovered and shall, I hope, shortly publish.—J. J. SYLVESTER.

Telegraphy without Wires, and the Guarding of Coast Lines by Electric Cable.

IT appears from an article in *Commerce*, December 16, that Mr. W. H. Preece, in a lecture on "Telegraphy without Wires," at Toynbee Hall, said, that from experiments at the Goodwin Lightship it had been found impossible to get a message on board, and "that the intervening sea-water performed much the same function as an iron plate," I would like to call the attention of the readers of NATURE to my paper laid before the Royal Society of Edinburgh in January 1893, when it was shown that neither salt nor fresh water had any appreciable effect on the transmission of these electrical waves. Take this case—an iron steamer afloat above a cable lying on the sea-bottom. If the steamer have on board suitable apparatus, messages sent along the cable from a single Leclanche cell can be and have been read on board ship by ordinary sailors. If it is possible to so convey messages to a vessel not moored by an anchor, it is surely possible to do the same to a moored ship such as a lightship. Mr. Preece's failure at the "Goodwin" is not due to the action of salt water, for, if electric vibrations work through salt water in the Firth of Forth, they will equally do so at the "Goodwin."

One word as to Prof. Boase and Mr. Marconi's systems. Although it may be impossible to say what system may be found best for the detection of the electric vibrations, there is one thing certain that it is needless refinement to try to send the vibrations for lighthouse work ten miles. The vibrations require to be sent only 600 feet, as it is possible to lay a cable guarding a stretch of fifty miles of coast, ten miles off the shore, in at most fifty fathoms of water, and send the vibrations along it, and whenever the ship comes within two hundred yards of the cable the detector on board would give the alarm. Further, the advantage of the cable system is great, as the vessel would know her exact distance off; whereas, by sending the vibrations from a point on shore, this would be impossible.

CHARLES A. STEVENSON.

84 George Street, Edinburgh, December 21.

The Origin of the Stratus-Cloud, and Some Suggested Changes in the International Methods of Cloud-Measurement.

IN his "Instructions for Observing Clouds" (London, 1888, p. 12), Hon. Ralph Abercromby defines *stratus* as "a thin uniform layer of cloud at a very low level," and as an illustration reproduces a photograph of a low sheet of cloud which he says is exceedingly characteristic of east winds in London. In his book "Weather," p. 48, he shows by a diagram that the position of the *stratus* is in the south-west quadrant of the anticyclone. By carefully plotting the observations made at the Blue Hill Meteorological Observatory during the past ten years, I find that this type of cloud has the same position in the anticyclones on the eastern coast of the United States that Abercromby found for England. Moreover the continuous records, made by instruments lifted by kites at the Blue Hill Observatory, furnish a very evident explanation of its origin. In a number of cases the recording instruments were lifted into or through such clouds, and in every case the temperature and humidity rose suddenly as the thermograph entered and passed through the stratus-cloud. This rise of temperature is not shown when the thermograph is lifted into cumulus or nimbus clouds. Hence it is evident that the stratus described by Abercromby is found at the plane of meeting between a cold current and a warmer, damp current overflowing it. The cause of the stratus is undoubtedly the mixture between the two currents and the consequent condensation of moisture in the warmer current.

There is, however, another conception of stratus described by Prof. H. H. Hildebrandsson in his "Classification des Nuages employée à l'Observatoire météorologique d'Upsala," where he says: "One sees that the stratus of Howard is nothing but a fog; at Upsala we designate also, under the name of stratus, fog lifted above the earth, and which exists ordinarily as isolated fragments at a slight distance above the ground." In the Hildebrandsson-Köppen-Neumayer cloud-atlas a picture of one of these isolated fragments is given above the name of *stratus*; and the primary definition of stratus given in large letters is "Lifted Fog."

These two definitions of stratus by Abercromby and Hildebrandsson have apparently been taken as identical by their authors; but I think the facts mentioned indicate that they have no more in common, either in origin or appearance, than have cirrus or cumulus. When the International Committee met at Upsala it recognised the inadequacy of the illustration of stratus given in the Hildebrandsson-Köppen-Neumayer atlas, and, like Abercromby, *pictured* stratus as a thin sheet of low cloud, but *defined* it as "Lifted fog in a horizontal stratum." This compromise between two entirely different conceptions of stratus results in an absurdity. Lifted fog rarely or never forms in a horizontal stratum. Certainly, during ten years of daily observations of clouds, I have not seen such a phenomenon, nor have I seen it described by writers on the subject. Moreover, if lifted fog ever does form in a horizontal stratum, how can an observer know, when he sees a stratus, whether it is lifted fog or is a cloud formed by mixture? I trust at some future meeting of the International Committee this definition may be changed. Probably the authors of the definition will not object to the change, now that the observations with kites have thrown a new light on the origin of stratus.

Another point to which I think the attention of those engaged in the international scheme of measuring the heights and velocities of clouds should be called, is the fact that measurements of cloud-heights by theodolites or photogrammeters give erroneous averages for certain forms of clouds. At Blue Hill Observatory, using every opportunity to measure the altitude of nimbus with theodolites, we find the average height by such measurements to be 2077 metres; yet in our measurements of cloud-heights, made by sending kites into them, we find that on more than half the days when nimbus is present its base is at an altidude of less than 1000 metres, and usually less than 500 metres. The average height determined from the kite-measurements is 497 metres, and by the angle above the horizon of the light reflected at night from the clouds over distant cities it is found to be 845 metres. Similar differences are found in the case of strato-cumulus. The reasons are that low clouds are so indefinite in outline, or they cover the sky with such a uniform veil, that they cannot be measured with theodolites or photogrammeters. It results that the clouds measured by theodolities are principally high clouds. On the other hand very high clouds cannot be measured with kites, and the average

height by this method is too low. The average determined from reflected lights (845 metres) is probably most nearly correct.

I think it is apparent that the observations with theodolites and photogrammeters at the international cloud-stations should be supplemented by other methods, if correct averages are to be obtained, and if clouds which cover the sky with a uniform veil are to be measured at all. Small balloons turned loose and followed with theodolites, suggested by Kremser, is a good method in such cases. H. HELM CLAYTON.

Blue Hill Meteorological Observatory, December 7.

Radiography.

YOUR correspondent, Mr. G. M. Lowe, asks for information as to the best methods of working direct on to sensitised paper to save the time and expenses involved in taking glass negatives. "Nikko" paper, as supplied by the Eastman Company, is a good substitute for glass plates, and the results on it are much superior to the smooth bromide papers. Eikonogen is a suitable developer—say five or six ounces of water to the contents of an eikonogen cartridge, and fix in clean hypo solution. Of course, to show the palma-surface of the hand when using a glass plate, the film side is *up* and the palm *down*; but in using paper direct, the film should be down, and the X-rays, therefore, pass through the paper before reaching the sensitive surface.

Radiographs made direct on paper are *negatives*, the bones being shown white. It has been stated that this is the correct way to show the bones, but it is quite a mistake. Bones are white by reflected light; by transmitted light they are black, more or less, and if X-rays are light rays, then the light is transmitted, and radiographs ought to be as usually shown printed from a glass negative; but for surgical purposes, for such as foreign bodies in the hand, negative or positive makes little or no difference. By the direct "Nikko" paper method the exposure must be longer, but to locate a needle in the hand thirty to forty seconds is sufficient. Two, three, or up to a dozen sheets of "Nikko" paper may be exposed at one time. Between the first and second sheet very little difference in exposure will be noticed, but between the first and, say, the twelfth the difference will be considerable. To extend this difference when only a few sheets are used, insert a piece of suitable black paper between each. W. I. CHADWICK.

The Heating of Anodes in X-ray Tubes.

I SHALL be much obliged if any of your readers who work with the X-rays will give me their experience with the 10-inch coils. I have one by Apps, which is excellent in every way; but whether I take from it a 2-inch or a 10-inch spark, the anode of the tube invariably becomes red or white hot within a few seconds.

The tubes are by leading makers, and exhausted for 8 or 10-inch sparks; but, as I have said, even a 2-inch spark makes the anodes red hot.

On the other hand a German coil I have, does not perceptibly heat the anode of the tube even when I use a 5-inch spark.

Is this the experience of others; and why should a 2½-inch spark from one coil make the anode red hot immediately, when a 5-inch spark from another coil does not do so?

This difficulty at present prevents me employing the Apps 10-inch coil at all for X-ray work. WALTER CHAMBERLAIN.

Harborne Hall, near Birmingham, December 19.

Units of Force.

IN your issue of December 10, Prof. O. J. Lodge makes several curious statements.

He speaks of "inertia multiplied by the square of a velocity." He might as well speak of "shapelessness multiplied by the cube of a length." Inertia is a word best left unused, but usually means a property of what is called matter—like whiteness, hardness, inextensibility.

He also speaks of natural formulæ "independent of every system of units that can be devised," and, though he only gives one formula, implies that every mathematical relation can be expressed in a similar manner. Will he be so good as to give a formula connecting the weight, volume, and specific gravity of a body which is "independent of every system of units"?

As to the poundal, the objection to it is that no one uses it in actual work. There may be other objections, but that is a sufficient one.

As to teaching elementary mechanics, I am convinced that we should avoid "mass" as much as possible. When dealing with a particle, express Newton's Second Law by the formula $P/Q = f/a$, where P and Q are the forces producing accelerations f, a, respectively. This will usually take the form $P/W = f/g$. Then you may use any unit of force you choose, and the energy formula becomes $P \times s = W\frac{v^2}{2g}$, which may be in inch tons, foot pounds, or what you please. Is it too much to hope that the poundal may be shortly relegated, even in text-books, to that place, wherever it is, where grades are employed for measuring angles? C. S. JACKSON.

R.M. Academy, Woolwich.

The Distance of the Visible Horizon.

HAS not Prof. Lodge in his enthusiasm, which I fully share, for an absolute system of measurement rather overstepped the mark when in the equation $2R\,h = d^2$ for the distance of the visible horizon, he says that "h is not the number of feet, or of metres, or anything else, it is the actual height; d is not the number of miles or of inches to the horizon, but it is the distance itself; and similarly 2 R is the diameter of the earth, and not any numerical specification of that diameter (see NATURE, vol. lv. page 125). Surely the equation as written is an algebraical equation, and, as such, the symbols it contains express numbers and not things. The multiplication as he implies of one length (2 R) by another length (h), is abhorrent to the mind of "the Cambridge mathematician." The superiority of the formula over the mutilated apology for it which Prof. Lodge quotes, lies in the fact that the equation is true in terms of any conceivable unit of length in which the three lengths involved in it are measured. I am of course aware that the particular formula given may be regarded as an abbreviated statement of the approximate geometrical proposition that the rectangle contained by the diameter of the earth and the height of the observer above its surface equals the square on a line equal to the distance of the visible horizon, in which case, of course, Prof. Lodge's description of the symbols would be accurately true; but I do not think that the formula with this interpretation really illustrates his meaning.

I wish to associate myself with Prof. Lodge in his condemnation, for educational purposes, of all formulæ of the engineer's pocket-book type, should it unfortunately happen, that they gain a footing on the scientific side of school instruction it will do much to justify the slur, still too often cast, on science teaching at schools and at the universities, that it is not education. This must be my apology to Prof. Lodge for thus emphasising a mere *lapsus calami*. L. CUMMING.

Rugby, December 12.

Position of Boughs in Summer and Winter.

THE following measurements may perhaps be of interest. They have been made with a view to ascertaining how much the weight of leaves and fruit depressed the branches of a tree. The first measurements were taken on August 3, the second on December 14, 1896:—

Height from Ground in inches.

	August 3.	December 14.
Mulberry tree—		
Lowest twig	0 in.	31 in.
Higher branch	59 in.	72 in.
Another branch	20 in.	39 in.
Walnut tree—		
Lowest twig	15 in.	34 in.
Higher branch	60 in.	76 in.

In the case of the first branch of the mulberry tree, it was found in December that a weight of 35 pounds was not sufficient to lower it to its summer position. AGNES FRY.

Failand, near Bristol, December 15.

The Cultivation of Woad.

WITH reference to the letter of Rosa M. Barrett, in NATURE of November 26, p. 79, I formerly lived for many years, and my father before me, in the part of Somerset to which your correspondent alludes, viz. the neighbourhood of Bath, and within a few miles of Mells, I never remember to have seen or

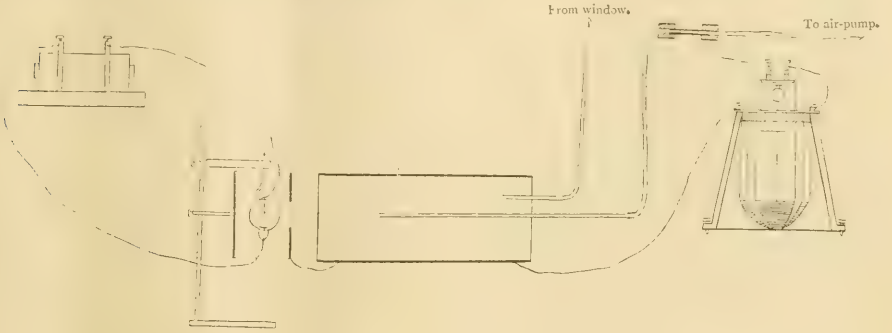
heard of the cultivation of woad, *Isatis tinctoria*; but "wood-wax" (? woad-wax), *Genista tinctoria*, which grows plentifully in that neighbourhood in pastures on marly soil, used to be collected by the peasant-women for dyeing purposes at the cloth factories in Trowbridge. The plant being very tough to pull up, "wood-waxing" was very laborious work. I am not aware whether it is still carried on there.

Croydon, December 16. H. FRANKLIN PARSONS.

ELECTRIFICATION OF AIR BY RÖNTGEN RAYS.[1]

TO test whether or not the Röntgen rays have any electrifying effect on air, the following arrangement was made.

A lead cylinder 76 cms. long, 23 cms. diameter, was constructed; and both ends were closed with paraffined cardboard, transparent to the Röntgen rays. Outside the end distant from the electrometer (see diagram) a



Röntgen lamp[2] was placed. In the other end two holes were made, one in the middle, through which passed a glass tube (referred to below as suction pipe) of sufficient length to allow the end in the lead cylinder to be put into any desired place in the cylinder. By means of this, air was drawn through an electric filter[3] by an air pump. The other hole, at a little distance from the centre, contained a second glass tube by which air was drawn through indiarubber tubing from the open-air quadrangle outside the laboratory.

In one series of experiments the end of the suction pipe was kept in the axial line of the lead cylinder at various points 10 cms. apart, beginning with a point close to the end distant from the Röntgen lamp.

In every case the air drawn through the filter was found to be negatively electrified when no screen or an aluminium screen was interposed between the Röntgen lamp and the near end of the lead cylinder. The air was found not electrified at all, or very slightly negative, when a lead screen was interposed.

When the Röntgen lamp was removed or stopped, and air was still pumped through the filter, no deflection was observed on the electrometer. This proved that the air of the quadrangle was not electrified sufficiently to show any deflection when thus tested by filter and electrometer.

Similar results were obtained with the end of the suction pipe placed so as to touch the floor of the lead cylinder, or the roof, or the sides. Whether the air was pumped away from a place in the cylinder permeated, or from a place not permeated, by the Röntgen rays, it was in all cases found to be negatively electrified.

The following are some of the results obtained on December 16 and 17. The electrometer was so arranged as to give 140 scale divisions per volt.

Conditions.—Large lead cylinder metallically connected with sheath of electrometer. Röntgen lamp surrounded by a lead sheath, which latter was also connected to electrometer-sheath. There was a window in this lamp-sheath 2·5 cms. broad and 5 cms. high. This window could be screened by aluminium or by lead. These screens were always connected metallically to sheaths. During all the experiments a Bunsen lamp (not shown in the diagram) was kept constantly burning, with its flame about 30 c.m. below the Röntgen lamp.

Results.—Röntgen lamp in action; air drawn from lowest point of end of lead cylinder next to the R. lamp.

December 16:—

3·55 p.m.	− 61 scale divisions in 2 mins.	with	aluminium	screen.	
	− 63 ,, ,, 2 ,,			no screen.	
	− 14 ,, ,, 2 ,,			lead screen.	
4.20 p.m.	Air drawn from point on lowest line of lead cylinder 26 cms. distant from R. L. end.				
	14 scale divisions in 2 mins.	with	lead	screen.	
	− 78 ,, ,, 2 ,,			no screen.	
	− 24 ,, ,, 2 ,,			lead screen	
	− 83 ,, ,, 2 ,,			alumin. screen.	
	− 13 ,, ,, 2 ,,			lead screen.	

December 17. R.L. acting, and air drawn through filter.

We had previously made experiments with a sheet-iron funnel 1 metre long, 14·5 cms. diameter; and with a glass tube 150 cms. long, 3·5 cms. diameter; and with an aluminium tube 60 cms. long, 4·5 cms. diameter. Air was pumped from different parts while the Röntgen rays were shining along the tube from one end, which was closed by paraffined paper stretched across it. In every case the air was found to be negatively electrified.

[1] "Electrification of Air by Röntgen Rays." By Lord Kelvin, Dr. J. C. Beattie, and Dr. M. Smoluchowski de Smolan. (Read before the Royal Society of Edinburgh, Monday, December 21, 1896.)

[2] The Röntgen lamp was a vacuum vessel with an oblique platinum plate (Jackson pattern).

[3] Kelvin, Maclean, Galt, *Proc. R.S.*, London, March 14, 1895.

In those earlier experiments the air drawn away was replaced by air coming in from the laboratory at the open end of the tube. We found evidence of disturbance due to electrification of air of the laboratory by brush discharges from electrodes between the induction coil and Röntgen lamp, and perhaps from circuit-break spark of induction coil. These sources of disturbance are eliminated by our later arrangement of lead cylinder covered with cardboard at both ends, as described above, and air drawn into it from open-air outside the laboratory.

We have also found a very decided electrification of air—sometimes negative, sometimes positive—when the Röntgen rays are directed across a glass tube or an aluminium tube, through which air was drawn from the quadrangle outside the laboratory, to the filter.

A primary object of our experiments was to test whether air electrified positively or negatively lost its charge by the passage of Röntgen rays through it. We soon obtained an affirmative answer to this question, both for negative and positive electricity. We found that positively electrified air lost its positive electricity, and in some cases acquired negative electricity, under the influence of Röntgen rays; and we were thus led to investigate the effect of Röntgen rays on air unelectrified to begin with.

Note on Diagram.—For the sake of simplicity, the screening of the electrometer is not shown in the diagram. In carrying out the above experiments, however, we have found it absolutely necessary not only to surround the electrometer with wire gauze in the usual manner, but we have had also to place a sheet of lead below it, and to screen also the side next the Röntgen lamp by a lead screen. In some cases it was even necessary to cover up the whole with paper to prevent the electrified air of the room from disturbing the instrument.

ON A NEW LAW CONNECTING THE PERIODS OF MOLECULAR VIBRATIONS.

AFTER the attempts to detect harmonic ratios in the wave-lengths of the light emitted by incandescent gases had failed, Balmer led the way in a line of research which promises to furnish a rational explanation of the different periods of a vibrating molecule. If τ_0 is a constant, the frequencies of all the hydrogen lines can be represented by Balmer's formula:

$$\tau = \tau_0\left(1 - \frac{4}{m^2}\right)$$

where for m we must put successively 3, 4, &c., and lines have been observed as far as $m = 15$. We may call τ_0 the convergence frequency, as it is that to which the vibrations approach as m increases. We also call the slowest vibration of the series the "fundamental." For other spectra the relationship is not quite so simple, but confining ourselves to the alkaline metals, the spectra of which have been most carefully examined and discussed by Kayser and Runge, these authors show that the vibration frequencies may be represented by means of three series of the form

$$\tau = A - \frac{B}{m^2} - \frac{C}{m^4} \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot$$

the fundamental in every case being given by $m = 3$. The first, or principal series, has lines which are single in the spectrum of lithium, but double in the other cases, the components separating further and further as the atomic weight increases. The two supplementary series consist of lines which easily widen and show the remarkable property that the convergence frequency A has nearly the same value for both supplementary series.

I must refer to Kayser and Runge's paper for a discussion as to how far the formula is approximate only, as well as to other details; but as the majority of physicists have not hitherto paid much attention to this subject, I may add the remark, that the division of spectra into a number of series of the above nature is by no means arbitrary, but constitutes a most important step in the simplification of a very complex problem. It is known that Runge and Paschen have shown that the constituents of cleveite gas have spectra resembling those of the alkali metals; and I hope in a future communication to show that the spectrum which I have called the compound line spectrum of oxygen also divides into three series of the same type.

As regards my new law, it is so simple that it is astonishing how it could so long have remained unnoticed. It may be enunciated as follows:

If we subtract the frequency of the fundamental vibration from the convergence frequency of the principal series, we obtain the convergence frequency of the supplementary series.

The following table shows how far the law is accurate:

	A (Principal Series)	Wave Number of Fundamental Vibration	Difference	A (Supplementary Series)
Lithium ...	43585 ...	14907 ..	28678 ...	28667
				28587
Sodium ...	41537 ...	16960 ...	24577 ...	24566
		16977 ...	24560 ...	24547
				24496
				24476
Potassium...	35087 ...	12988 ..	22099 ...	22077
		13045 ...	22042 ...	22022
				22050
				21991
Rubidium...	33762 ...	12579 ...	21183 ...	21179
		12802 ...	20960 ...	20939

The numbers given in the table are proportional to the frequencies, being inverse wave-lengths in centimetres. The two numbers given in the second column refer to the two components of the double lines. As the lines of the supplementary series are double in the spectra of sodium and potassium, there are the four convergence frequencies in these cases which are all given. In comparing the two last columns it must be remembered that the quantity denoted by A, which is the convergence frequency, cannot be determined with the highest accuracy because Kayser and Runge's formula is approximate only and fails to give accurate results for the case $m = 3$. The only serious differences between the third and fourth columns occur in the two cases in which Runge and Paschen used the case $m = 3$ in determining the constant.

In the case of cæsium, the fundamental vibration lies in the infra-red, and has not been observed, but we may use the law to forecast its position, and obtain a wave-length of 8908 for the less refrangible, and of 8518 for the most refrangible component, numbers not differing much from Kayser and Runge's estimate for the same lines. The numbers given by Runge and Paschen for the gases from cleveite are sufficient to show that the law also holds in the case of both sets of the three series into which the spectrum divides itself. In the case of oxygen, I have not obtained sufficient data as yet to determine the position of the principal series, as it lies chiefly in the ultra-violet, and the lines measured so far belong nearly all to the supplementary sets.

The supplementary series have not been observed in the spectrum of hydrogen, but the new law shows that if they exist they must lie in the infra-red, and it is with some confidence that I predict the existence of hydrogen lines in the infra-red, the convergence frequency being 1218·51 ($\lambda = 8206{\cdot}6$).

Attempts to obtain other similar relations in the spectra of gases have not so far led to any results. If the differences between the frequencies of the fundamental and the higher members of the principal series are taken, we obtain numbers not far distant from the frequencies of the first subordinate series, but this is only a consequence of the facts that the value of B in Kayser's formula does not vary much, and no importance can be attached to these coincidences, which are only very approximate. A few reflections concerning Kayser and Runge's equation may not be out of place here. The different periods of the same series have every appearance of having the same relation to the fundamental vibration as the overtones have to the fundamental of a sounding body. A word is much wanted to express for molecular vibration what corresponds to an overtone in sound. The term "harmonics" is sometimes used, but is not appropriate, as an overtone may or may not be harmonic to the fundamental. I suggest the expression "overperiod." In a sounding body the frequency of the overtones gradually increases without limit, but the overperiods observed in the spectra of elements gradually approach a definite limit, which we have called the convergence frequency. We may imagine a number of particles in a row, and raise the question whether we can imagine some connection between them such that they should be able to vibrate in a series of periods similar to those observed in the spectra of gases. If the particles are detached like those of Reynolds' disconnected pendulums, all overperiods would be equal, and it does not seem impossible to imagine some connection such that for the lower overperiods the connecting forces regulate the frequency, while for the higher overperiods the frequency tends to become equal to that of the separate particles. Looked at from a different point of view we may say that, if we could imagine a rod having elastic properties such that the relation between the velocities of a wave along it and the wave-length is

$$V = a\lambda - b\lambda^3$$

it would, if vibrating freely, give out a number of notes, the relative frequency of which would be the same as that of the luminous vibrations given out by a hydrogen molecule. ARTHUR SCHUSTER.

THE EARLY LIFE OF NANSEN.[1]

THIS volume was compiled at a time when the early confidence in the success of the great Arctic effort had given place in Norway to a feeling of anxiety, if not of alarm. The translation is now published when the preliminary narrative of Nansen's triumphal procession across the polar area has cast his former exploits into the shade, and the expectancy with which the complete account of the expedition is awaited by the public will not be appeased by the book before us. It comes, in fact, a trifle inopportunely. To modify a wearied metaphor, the play of *Hamlet* is cut short before the central scene; the Scandinavian Prince has just begun to absorb attention when the curtain falls. The book is also heterogeneous in a high degree; no less than six authors are concerned in it, and the fact that all the varied contributions are translated by the same hand, robs them of some of their original freshness, although the translation is really done very well. Perhaps the unifying principle of the ill-arranged chapters may be found in "Peer Gynt," copious quotations from which are scattered over the pages. An abstract of that famous work would have proved no bad substitute for the tedious chapter on the Great Ice-Age, which, even when abridged by the translator, has little to do with the other subjects considered. The chapters on the outfit of the *Fram*, her voyage to the Kara Sea, and Baron Toll's adventurous sledging expedition to the New Siberian Islands, should have been left for the forthcoming work on the polar expedition, a fact which will make them none the less interesting to the general reader. The chapter devoted to an interview with Mrs. Nansen is a clever piece of journalism, but of doubtful taste.

So far as the work is biographical it is welcome and fairly satisfactory. It is natural that the world should wish to know something of the personal life of the men who perform great achievements, and it is proper that this wish should be gratified.

No one has ever met Nansen without being struck by his remarkable personal charm. This happened to be the first fact I knew about him. A friend, who had been spending a holiday in Norway nine years ago, told me, on his return, that what most impressed him there was the appearance and the kindness of a stranger who had shown him the way while lost in the tortuous lanes of Bergen, and who, on saying good-bye, mentioned that his name was Nansen. When Nansen came to this country after the Greenland expedition, the curious magnetism of his presence at once recalled the forgotten remark heard two years before. A similar experience, occurring to many people, is frequently referred to in the biography.

Nansen was not the first Arctic hero of his family, the record of his ancestry beginning appropriately with an account of old Hans Nansen, who, born in 1598, explored the White Sea, and spent many years in command of a vessel in the Iceland trade. He combined literary work with his navigation, and wrote a "Compendium Cosmographicum," wherein he treated of the heavens and the earth, and described Arctic routes so well that a copy of the book was found in use in the year 1841, in preference to more modern sailing directions. More immediate ancestors on both sides were persons of strong character, although their interests and activity lay in other departments; and the authors trace to them, with some skill in the application of the laws of heredity, the blending of poetic and æsthetic feelings with the reckless daring and unalterable determination of Fridtiof Nansen's character.

Born in 1861 at Great Fröen in West Aker, near Christiania, Nansen was not long in showing his love for adventure, carelessness of danger, and disregard of pain. His father, a member of the legal profession, was a stern disciplinarian, but the discipline was judicious and directed to the development of character; his mother was remarkable for her determination and practical resourcefulness; she was also an enthusiastic snow-shoe runner, before that pastime became the common sport for ladies it now is.

Nansen's school-life is briefly traced, and his enthusiasm for athletic exercises and sport of every kind treated more fully and sympathetically, with extracts from his own early letters. Entering the Christiania University in 1880, he decided, after some hesitation, to take up zoology as his special study. Two years later he made his first acquaintance with the Arctic regions during a cruise on the *Viking*, which, while unfortunate from the owner's point of view, was full of opportunities for zoological observations and, above all, for polar-bear hunting on the east of Greenland. The story of this voyage is graphically told from the unpublished diary kept by Nansen. Immediately on his return to Norway, the curatorship of the Bergen Museum was offered to him, and eagerly accepted, as it afforded exceptional opportunities for zoological research. Here Nansen was under the direction of Dr. Danielssen, the founder of the museum, a tireless worker, and a true friend. In his farewell letter in 1893, Nansen wrote:—

[1] "Fridtiof Nansen, 1861–1893." By W. C. Brögger and Nordahl Rohlfsen. Translated by William Archer. Pp. x + 402. (London: Longmans, Green, and Co., 1896.)

"If I should grow weary or slack, the thought of your strength of will and your untiring activity will spur me on as it spurs on many and many another. A thousand good-byes until we meet again."

They never met again; the old enthusiast died in 1894.

While engaged on the study of the sex of *Myxine*, and the nervous system of invertebrates at Bergen, Nansen did not neglect his physical training. A feat scarcely surpassed for actual danger and reckless courage by any of his later Arctic adventures was his crossing of Vosseskavlen on snow-shoes in midwinter. In 1886 there came a visit to Dohrn's Biological Station at Naples; but the strictly biological studies were dropped in the following year, when the plan of crossing the Greenland ice-sheet had been definitely formed. It is not necessary to recount this achievement, the success of which raised Nansen at once to one of the highest places amongst Arctic travellers, brought him a shower of distinctions, and prepared the way for the triumph of his Arctic drift.

Hans Nansen

That Nansen has found his sphere in the work of polar exploration is undoubted. By race, ancestry, and upbringing, adventurous travel was his inevitable destiny, and success was assured by a combination of qualities which are rarely found together. His marvellous physique comes first, making him as nearly impregnable to cold, fatigue and hunger as ever man was; then his equally remarkable determination and daring, qualities of mind which urged his physical powers to the uttermost, and made retreat from any path once entered upon an impossibility. His friends knew that if Fridtiof Nansen did not return successful from any quest, he would never return at all. The principle which most shocked previous Arctic explorers was his rule of providing no means of retreat, in fact of making retreat impossible—the principle of *Fram*. These qualities of body and mind are frequently combined in "record-breakers" of every kind; their combination may result in a champion prize-fighter, a professional football player, a 30-mile-an-hour cyclist, a peak-conquering mountaineer; they ensure, in fact, merely a forced-draught motive power. The third element is that of training, the educational discipline of home and school succeeded by the scientific discipline of the university and the laboratory. This gave direction and controlling power to the fervid energy; but the capital importance of this fact has not been adequately set forth in the biography. It may have been recognised by the authors, but it has been obscured by a quite unnecessary mass of irrelevant matter. A case like this is a splendid proof of the superiority of scientific education over any merely classical teaching in developing the whole power of a man.

We believe that Nansen owed his success in both his great journeys to the fact that he could himself study the conditions he had to meet, and plan his method of meeting them; that having studied and formed his plans himself, he could also carry them out himself with the aid of a few devoted companions. The contrast of the expeditions planned by a large Committee, and executed

Fridtiof Nansen.

by a large crew under orders they cannot deviate from, is quite apparent. The plan suggested for obviating railway accidents, by mounting a director in front of the engine, was that which Nansen adopted. He was ready to stake his life on the accuracy of his methods; and if his biological studies did not settle the problems of the nervous system, or even of the hag-fish, they certainly disciplined his powers of observation and of reasoning, and so enabled him to succeed and to excel in his chosen career.

A few slips in translating or printing may be pointed out. On p. 80 we read, "He pursues the paltriest insect revealed by the microscope, no less impetuously than he pursued the bears over the Arctic wastes." Here *insect* stands apparently for the fine old *animalcule*, although *paltriest* is even in that case a curious word to use with reference to an object of biological research. On p. 119, "the English zoologist G. P. Cunningham" should, of course, be J. T. Cunningham. In comparing the cold of the Greenland Ice-cap with that of Northern Siberia,

the very important correction to sea-level is apparently left out of account (p. 205), but the passage is not clear. It was the younger, not the elder, Ross (p. 241) who conducted the successful Antarctic expedition. The historic drift of the *Hansa* in the ice was not "from Smith Sound right down to Davis Strait" (p. 281), but, as correctly given at two other places in the book, along the east coast of Greenland. The "geographical congress which lasted a week" (p. 289) at Newcastle in 1889, was the British Association, Section E of which was addressed by Nansen. On p. 291 the remarkable statement that Dr. Nansen was presented by the Royal Geographical Society with "the patrons of the Victoria medal," is resolved, on reference to the authority cited, into "the Patron's or Victoria Medal."

We miss any statement in the preface as to whether Dr. Nansen gave his approval to the publication of this translation of a work which was compiled in his absence, from data which must have been very incomplete. We are reluctant to suppose that his friends would, without his express sanction, have published so much of a purely personal and, sometimes, of a private nature, and the suspicion that they may have done so should have been made impossible. HUGH ROBERT MILL.

CELEBRATION OF PROF. CANNIZZARO'S JUBILEE.

WITH an impressiveness worthy of the high scientific value of the man who was honoured, the seventieth birthday of Prof. Stanislao Cannizzaro was celebrated on November 21 in Rome. In the wide amphitheatre of the Chemical Institute of the Royal University, in the same place where the illustrious investigator's activity was continually shown, many of the highest and most distinguished persons of the Eternal City met to do honour to him. Colleagues, friends, pupils collected to pay to this renowned chemist their tributes of esteem, veneration and affection, and in these feelings the whole scientific world joined.

No company more distinguished ever sat in those school benches. There were Senators Cremona, Tomasi-Crudeli, Todaro, Blaserna, ex-Minister Bacelli, Profs. Beltrami, Grassi (Darwin Medallist), Strüver, Luciani, Cerruti, Helbig, Bovio, Prof. W. Longuinine of Moscow, and many others.

When, accompanied by the President of the Council, Marquis Di Rudinì, by the Under-Secretaries of State, Hon. Galimberti and Arcoleo, by the Prefect Count Bonasi, and the Rector Magnificus, Prof. Semeraro Cannizzaro entered the hall, the audience burst into long and loud applause.

Prof. Senator Paternò opened the proceedings by saying that the Committee spontaneously formed among Prof. Cannizzaro's students has been obliged to confine itself to a few things, not for want of means, as many offers were sent from various parts of the world, but on account of the desire of Cannizzaro himself. Prof. Paternò presented a gold medal of admirable workmanship, which at one side holds in relief Cannizzaro's imagine, and at the other the following inscription: "To Stanislao Cannizzaro scholars and admirers, on the occasion of his seventieth birthday." He presented also an artistic bust of Cannizzaro in bronze from one of his English admirers, and numerous pergamenas, addresses, letters, telegrams, sent by the most important scientific Societies of the world. An address was sent by the Royal Society of London; and the Faculty of Science in the University of Heidelberg sent a pergamena in Latin. Among the bodies which sent letters of congratulation were the "Académie des Sciences de Belgique," the Italian "Accademia dei Quaranta," and the Academies of Turin, Naples, Bologna, Venice, Milan, Catania. The Academy of St. Petersburg sent the following telegram.

"L'académie impériale des sciences rempli de consideration pour les travaux de l'illustre savant participe aux voeux et felicitations unanimes à l'occasion de son jubilée.

"Le sécretaire perpetuel,
"General Lieutenant Doubrovine."

Among the foreign Chemical Societies, those of London, Berlin, St. Petersburg, the American Chemical Society sent addresses:

Congratulatory letters and telegrams were also received from the Société chimique de Paris, Bucarest, Heidelburg, Munich, from the *Verein Deutscher Chemiker*, from the Chemical Society of Finland, the Badische Anilin und Sodafabrik, the Chemical Laboratories of Tübingen, Bucarest, Lisbon, and from all the Italian Universities. The Chemical Society of Aix-le-Chapelle sent a pergamena.

Among the most eminent persons who sent their best wishes to Cannizzaro, we take notice of the following: Lieben, Baeyer, V. Meyer, Mallet, Alnovillicus (Erlenmeyer, sen), Curtius, Wislicenus, Hantzsch, Fittig, &c., General Annibale Ferrero, Italian Ambassador at London, Ministers Guicciardini and Codronchi, Prof. Cosfa (Turin), Prof. Ugo Schiff (Florence), &c. The University of Kasan have made Cannizzaro Honorary Professor on this occasion; and the Grand-Duke of Baden conferred on him the "Komandeurkreuz 1ᵉ Klasse des Zähringer-Löwes."

Prof. Semeraro, Rector Magnificus of the Roman University, delivered the following address:—

"This festival does not only belong to the University of Rome, but also to the world's science. Cannizzaro's work is to be considered as having two parts, the one dear to the world, the other dear to us. We have seen the former in the addresses, letters, telegrams sent on this occasion; the latter is to be found in his teaching career, which is nearer to his heart.

"When Cannizzaro received the Copley Medal, the celebrated man said, he has been but a teacher, he had but loved the school and his pupils. My science, said he, has been the aim of my life for their instruction and warfare.

"His greatest glory lies in the fact that most of the professors now teaching in Italian Universities have been his scholars. The pressure of business, as Vice-President of the Senate, and Member of the Superior Council of Public Instruction, and many others, never were pretexts to him for overlooking the modest duty of a teacher. That is what makes him glorious in our University.

"Since Cannizzaro was admitted in Senate for his own scientific merits, he has never rested. He acquired from the Government the means for studying, and creating the first great Italian chemical school, and we all have seen what a happy success he has obtained by these means.

"To-day we can say on Cannizzaro what is said in an ancient inscription of a great Roman church, '*Virtude vixit, fama vivit, gloria vivet!*'"

In presenting to Cannizzaro the Grand Cordon of the Crown of Italy, Hon. Galimberti, Under-Secretary at the Public Institution Office, said:—

"This adds nothing to your fame, but is a proof that your own Government joins with those around you in their congratulations. People could give you this decoration with greater title, but none with greater affection and devotion than I do. Your name, as the Royal Society of London has said, is worthy of being joined with those of Galileo, Torricelli, Volta, and Galvani. To Emanuel Kant, who, in his absolute sentence, considered chemistry as a union of empirical knowledge, you replied half a century ago, pronouncing among the

confusion of doctrines immovable ideas and true laws as to render chemistry an exact science, for it lies now on mathematical truth."

Cannizzaro replied to the congratulations in an interesting speech, which we hope to refer to more fully in a future issue. In the course of his remarks he referred to the confusion and uncertainty which dominated chemistry between 1850-51 on the criterions for determining atomic weights and on the value of formulæ, giving an account of the attempts made by others and himself to reduce chemical notation to law and order.

He afterwards referred to the subject of the division of pure science from teaching. He cited De Candolle's book, "Histoire des Sciences et de Savants," to the effect that the two functions of teaching and contributing to the science progress are to be separated. De Candolle hoped for the time when academies would be formed by free investigators. Cannizzaro is of contrary opinion, and dwelt upon the utility of teaching. He said: "Had I not been a teacher, my publications would not have appeared, and I should have continued to disseminate science of new carbonium compounds. I bring here Lord Kelvin's example, who, in his last jubilee, spoke of the utility he had found by the continued conferences with his scholars."

In speaking upon chemical laboratories, Cannizzaro expressed the opinion that the Director ought to dwell in the same building where the laboratories are situated. He thinks the German type of laboratory the best of all; for he said: "The chief must be considered in a scientific institute as the first, and more useful instrument."

Cannizzaro concluded by referring to the large sum obtained by subscription on occasion of his jubilee, and devoting the remainder of it to the extension of the Roman laboratories.

The celebration was concluded amid great enthusiasm and prolonged applause. A. MIOLATI.

THE FINAL ENTOMBMENT OF PASTEUR.

THE remains of Pasteur, which for nearly fifteen months have been lying at Notre Dame, were on Saturday, Dec. 26, borne in solemn procession to their last resting-place at the Pasteur Institute, where a crypt worthy to hold the ashes of that great benefactor of the human race has been constructed. The subjoined report, slightly abridged from the *Times*, shows that the ceremony of the final entombment was an impressive one, and that representatives of British science were among those who, by their presence and their words, testified to the high regard in which the name of Pasteur is held.

As at the original funeral, there were present a number of eminent men of science and thinkers, both French and foreign, and the ceremony derived additional grandeur from the gathering which witnessed the final interment. The man whose ashes lie in this tomb erected by filial piety and universal admiration is depicted in a sentence from his reception speech at the Academy which the architect has inscribed on the stone: "Heureux celui qui porte en soi un dieu, un idéal de beauté, et qui lui obéit—idéal de l'art, idéal de la science, idéal de la patrie, idéal des vertus de l'évangile." The English deputation included Sir Joseph Lister, President of the Royal Society, Sir Dyce Duckworth, Sir John Evans, and Sir William Priestley. Dr. Metchnikoff represented Russia, and Dr. van Hoorn Holland. M. Méline and M. Rambaud represented the Government, and M. Brisson, a number of ex-Ministers, Senators and Deputies, many members of the Institute and the Prefects of Police and of the Seine were among those present.

There was, first of all, a service at Notre Dame, attended by the family and the staff of the Pasteur Institute, who then, with the archpriest, followed the hearse to the Institute. A crowd had collected outside, and amid an impressive silence every head was bared as the coffin was carried up the steps through the grand vestibule and down to the crypt, which was decorated by the wreaths sent by English, Russian, and French societies and institutions. The parish priest pronounced the last prayers as the coffin was deposited in its last resting-place in the presence of the family. They then remounted the steps to the entrance of the crypt, where all the spectators were stationed, and M. J. B. Pasteur, addressing the Council of the Institute, said: "I entrust to you this tomb which we have raised to our father in this Institute which he loved so dearly. We beg you to preserve it carefully." M. Bertrand, President of the Council, thanked the family for their pious idea, thanks to which, he said, the pilgrims who would come from all parts of the world to honour the memory of the great benefactor of mankind would be able to meditate by his tomb. M. Rambaud, Minister of Education, next delivered a warm eulogium. "As those tombs of saints," he said, "on which people saw prodigies accomplished, that of Pasteur will be encircled by a halo of miracles. At every discovery beneficial to mankind, at every ray of scientific glory which will be added to the aureole of France, the gratitude of the country and of the universe will flow to this building, henceforth august in the annals of science, as to the source of all ulterior progress." M. Baudin, President of the Municipality, was the next speaker, and an address by M. Legouvé, the father of the French Academy, was read by M. Gaston Boissier.

Sir Joseph Lister then said: "Je suis chargé de représenter la Société Royale de Londres, le Collége Royal des Chirurgiens d'Angleterre et la Société Médico-Chirurgicale de Londres. Aussi j'ai fait déposer, de la part de l'Institut Britannique de la Médecine Préventive, fille de l'Institut Pasteur, une couronne ici. Il y a quatre ans, à l'occasion du jubilé de Monsieur Pasteur, j'ai eu le suprême honneur de lui présenter, au nom de la Médecine et de la Chirurgie du monde entier, l'hommage de leur reconnaissance. Aujourd'hui j'assiste à ses funérailles! Cette cérémonie est noble et imposante, digne de la mémoire de notre vénéré maître. Mais elle nous remplit d'une profonde tristesse, puisqu'elle nous rappelle que cette grande lumière de la science, si ardente et si claire, est éteinte; que ce caractère, si noble et si aimable, a disparu de notre monde."

Sir Dyce Duckworth spoke as follows: "Au nom du Collége Royal des Médecins de Londres, j'ai l'honneur de témoigner la vive sympathie avec laquelle les médecins d'Angleterre s'associent à cette touchante cérémonie. Je porte l'hommage de nos confrères à ce grand génie créateur, à ce noble caractère de Louis Pasteur. Pour nous il est un des prophètes de la science, il en est un des avant-coureurs les plus éclairés et les plus intrépides. Vénérons ensemble ce bienfaiteur de l'humanité! Vénérons ce Chrétien loyal et convaincu, dont la foi a résisté à toutes les influences matérialisantes de ses études! Que l'œuvre de Pasteur, dont les cendres reposeront désormais dans ce sol consacré par son travail, reste une des gloires impérissables de la France et du monde!"

Sir W. Priestley said the two Scottish Universities of Edinburgh and St. Andrews appointed him as their representative, in token of respect for the memory of one who had done so much to advance the interests of science, and who had conferred such signal benefits on mankind. He remarked that Pasteur not only made great discoveries himself—discoveries which had conferred priceless benefits on man and on the lower animals—but he opened up new and hitherto unexplored paths in the field of science, the horizon of which was almost unlimited.

M. Cornu, for the Academy of Sciences, M. Bergeron, for the Academy of Medicine, M. Perrot, for the Normal School, M. Louis Passy, for the Agricultural Society, M. Tissier, for the medical students, and M. Duclaux, director of the Pasteur Institute, also spoke. A feeling of restrained emotion prevailed during the entire ceremony, at the conclusion of which the spectators passed respectfully before the tomb and greeted the widow and family of the illustrious investigator.

NOTES.

WE deeply regret to have to record the death of Prof. Emil Du Bois-Reymond, the eminent professor of physiology in the University of Berlin. Before his burial in the French cemetery in Berlin, on Tuesday, addresses were delivered in the Physiological Institute, of which Du Bois-Reymond was the founder. The Emperor and the Empress Frederick have telegraphed expressions of condolence to the widow and relatives of the deceased.

A BOTANICAL Institute has recently been opened in connection with the Botanical Garden at Münster, in Westphalia.

IN deference to public demand, the new aquarium of New York City will be open to visitors on Sunday after January 1.

THE report that M. Nobel, the inventor of dynamite, has bequeathed his property, estimated at fifty million francs, to the University of Stockholm, is contradicted.

A PLAN is proposed in the American botanical journals for the establishment of an American tropical botanical laboratory on the plan of that at Buitenzorg, either on the east coast of Mexico, or on one of the islands near the Caribbean Sea.

THE *Botanical Gazette* states that a notable cactus-garden has been established at the University of Arizona. It is the purpose to bring together eventually all the Cactaceæ indigenous to the United States; already more than one hundred species are represented.

PLANS have been prepared for the buildings in the Botanical Garden of New York City. The buildings, with their approaches, will occupy twenty-five acres of ground. They will be dispersed in different parts of the grounds, throughout the garden, and not grouped together.

WE regret to announce the deaths of Mr. G. F. Schacht, treasurer of University College, Bristol, and formerly vice-president of the Pharmaceutical Society of Great Britain; Dr. L. J. Sanford, formerly professor of anatomy and physiology in Yale University; and Dr. Emil Wolff, of Stuttgart, well known for his works in agricultural chemistry.

A VERY remarkable landslip occurred early on Monday morning, at Kathmore, about twenty miles to the east of Killarney, and on the confines of the county Cork. As a result, possibly, of the almost incessant heavy rains of the past few weeks, a considerable portion of bog land slipped from its position, and, taking a southerly direction, swept everything in its course for a mile or two. As a result of the slip a considerable tract of country has been submerged, and the rivers in the neighbourhood are flooded with peaty water.

THE Academy of Natural Sciences of Philadelphia has decided to confer the Hayden Memorial Award for 1896 upon Prof. Giovanni Capellini, of Bologna. Capellini was born in Spezia, August 23, 1833. While yet a student he had made important palæontological discoveries and was in correspondence with illustrious investigators, both Italian and foreign. In September 1859 he was appointed Professor of Natural History in the National College of Genoa, and in the following year he became Professor of Geology and Palæontology in the University of Bologna. The rich collections made by him in Nebraska and elsewhere, while on a visit to North America in 1863, are now in the Geological Institute of Bologna. In 1864 he made interesting scientific discoveries in the petroleum lands of Wallachia. As President of the Second Extraordinary Reunion of the Italian Naturalists in Spezia in 1865, he founded the International Congress of Anthropology and Prehistoric Archæology. He was made Vice-President of the First International Geological Congress in Paris in 1878, and obtained its assent that the second meeting should take place in Bologna in 1881. Elected actual President (in conjunction with Quintino Sella as honorary President) of this Congress, he inaugurated the commission for the unification of geological nomenclature and a commission for the production of a geological map of Europe, outlined at Berlin. Together with Sella he founded, on that occasion, the Italian Geological Society. In 1885 he directed, in great part, the third International Geological Congress in Berlin, and contributed not a little to its success, as also to that of the fourth session in London in 1888. He had now published 140 scientific communications. Having served as Rector of the University of Bologna at intervals from 1874 to 1888, in the latter year he organised and directed a celebration of its eighth century, for which he received letters of congratulation from all the universities of the world. He has been decorated by the Emperor of Germany and other Sovereigns. The University of Edinburgh conferred upon him through its Rector the diploma of Doctor "Honoris Causa." The University of Moscow nominated him honorary Professor. Seventy of the principal academies of Europe and America have registered his name among their members. He was elected a Correspondent of the Academy of Natural Sciences of Philadelphia in 1863.

THE American naturalists continue their researches into the variations and distributions of the multitudinous small mammals of North America with great industry. Besides the labours of Dr. Hart Merriam, to some of whose remarkable memoirs we have lately called attention, we have recently received copies of papers by Mr. G. S. Miller, jun., on the "Beach Mouse of Muskeget Island" (*Microtus breweri*), and by Mr. C. F. Batchelder on the distribution of various rodents in New England and Northern New York.

THE first part of vol. xviii. of Dr. Jentink's "Notes from the Leyden Museum," which we have lately received, contains mostly papers on entomological subjects. There are besides these, three communications from Dr. J. Büttikofer on birds, including the description of a new duck from the island of Sumba (*Anas salvadorii*), which presents rather anomalous characters. It is curious that many of the contributors to this Dutch periodical write in English (which is likewise the language of the title-page), though others use French and German.

SOME American naturalists have taken to give not only the year and month, but even the day and hour of the "distribution" of their "advance sheets." To such an excess is the rush for "priority" now carried! Mr. Outram Bangs has lately made out that the reindeer of Newfoundland (known to be abundant there since the discovery of the island) possesses certain differential characters from the continental forms, and names it *Rangifer terræ-novæ*, dating the notification of this important event on "Wednesday, November 11, 1896, at 5 o'clock p.m." We trust that no British naturalist has yet made the same discovery, or grave international complications may arise.

THE distribution in time of the after-shocks of earthquakes was successfully investigated two or three years ago by Prof Omori, of Tōkyō (see NATURE, vol. li. p. 423). In an interesting supplement to his valuable memoir, Prof. Omori discusses the after-shocks of the great Japanese earthquake of November 4, 1854, and shows that their decline in frequency obeys the same law as those of the more recent cases examined. The monthly number (y) of after-shocks at Tosa until the end of 1855 is found to be given very nearly by the equation $y = 225{\cdot}2/(x + 1{\cdot}098)$, where x is the time expressed in months, since December 1854. For the whole year 1895, this equation would give between five and six shocks, while, during the years 1885–91, the mean annual number of shocks actually recorded at Tosa was 4·3. The agreement is so close that Prof. Omori seems justified in regarding it as not accidental.

THE *Boletin de la Sociedad Geográfica de Madrid* contains a paper by D. Emilio Bonelli, describing recent explorations in the island of Fernando Po. The coast of this island has long been fully known, but the forest regions surrounding the Peak of S. Joaquin have not hitherto been penetrated. On an excursion round the Bay of Concepcion, Father J. Juanola, a missionary, found himself at the edge of a funnel-shaped chasm some 300 metres in depth. At the bottom of this funnel, probably the crater of an extinct volcano, was a lake about 1200 metres long and 800 metres wide at its broadest part, to which the name Lago Loreto was given. So far as appeared,

this lake had no outlet, and was fed by a subterranean stream; the surface was estimated at 1350 metres above sea-level, and the surface temperature of the water was 14° Réaumur.

DIRECTOR KELMERT has presented to the Prussian Academy of Sciences a memoir on the variations of the force of gravity along a line from Kolberg to the Schneekoppe, by Arnswalde, Gröditzberg, Grunau, and Giersdorf, founded on a combination of German and Austrian observations at twenty-two stations. A normal curve of change of intensity is drawn between the two points, and the departures from this curve at particular stations are discussed in detail. The *Mittheilungen* of the Geographical Society of Vienna contains an abstract of the results, which show that an abnormal increase in the force of gravity can be traced to the presence of dense rock masses below the surface, and an abnormal decrease to the partial or total removal of unexposed strata. Under certain assumptions it is possible to estimate the thickness of these subterranean strata; on the Pomeranian lake plateau a layer of about 210 metres in thickness is responsible for increased intensity, while near the Schneekoppe a decrease, which cannot be ascribed to lower density at the surface, is probably due to subterranean layers 200 metres in thickness. These disturbing elements do not in all probability lie deeper than 20 or 30 kilometres. The deflections of the plummet from the vertical are also discussed with interesting results; the maximum deflection, amounting to 18·1″, was observed at the Alter Bruch Station on the slopes of the Schneekoppe, at an elevation of 917 metres.

IN the current number of the *Atti dei Lincei*, Dr. G. Folgheraiter concludes his investigations on the state of terrestrial magnetism in the Etruscan epoch as revealed by observations of old vases (see p. 40). The results appear to indicate that in the eighth century B.C. the magnetic dip in Central Italy was small, and in the reverse direction to what it is at the present time, so that a magnetised needle at that epoch would have assumed a position with its south instead of its north pole pointing downwards. Some two centuries later, the declination seems to have approached the value zero, the earth's magnetic field being nearly horizontal, while in many of the vases the direction of polarity is the same as at the present time. There are, of course, many difficulties in the way of drawing precise conclusions from these observations—such, for example, as the uncertainty as to the date of fabrication of the vases; but the results are sufficiently consistent to establish the validity of the method. Dr. Folgheraiter points out that the prevalence of austral magnetism at the bases of Etruscan vases might be interpreted either on the supposition that the magnetic equator has been so displaced as to pass to the north of Etruria, or by admitting that the northern and southern hemispheres had their magnetic polarity opposite to that of the present time, and that the latter state may have been arrived at by successive variations in the magnetic declination. The present state of knowledge does not permit more weight to be given to one hypothesis than to the other; nevertheless, the author already has an idea of trying if it may be possible to throw some light on this question by means of suitable investigations.

THE latest number of the *Centralblatt für Bakteriologie*, Part ii., contains a paper by Messrs. Stutzer, Burri, and Maul, on the capability of growing on foreign culture media exhibited by the *Bacillus radicicola*. These bacilli have attracted a great deal of attention recently in connection with Dr. Nobbe's investigations. It will be remembered that Nobbe has isolated out seventeen or more of these nitrogen assimilating bacteria from the root-nodules of various leguminous plants, and has endowed them with the collective title of Nitragin. The present memoir describes some experiments made with these novel bacterial soil fertilisers derived from lucerne plants. Culture media were prepared from these plants, and also from white mustard plants, by adding to the infusions respectively derived from them, gelatine and grape sugar, the whole being then sterilised as usual. Lucerne-nodule-bacteria were inoculated on to both these different media, and their cultivation was carried on through several generations. Whereas on the lucerne gelatine the bacteria flourished abundantly up to the last, on the mustard gelatine they gradually faded away. It was next tried if these lucerne-nodule-bacteria could be induced to thrive on this mustard medium by gradually training them to become accustomed to this foreign soil. In the course of six months these bacteria had completed their education, and they accepted the mustard gelatine as eagerly as they had before the lucerne gelatine. This highly successful result led the investigators to think that possibly in the interval these bacteria might have lost all taste for their original culture food, but inoculation from these mustard-grown bacilli on to lucerne gelatine showed that this anticipation was not justified, for they grew with their usual luxuriancy. It would be interesting to determine if by suitable training nodule bacteria could be induced to fertilise or "nodulise" leguminous plants other than those from which they were originally derived.

ARCHÆOLOGISTS have long been puzzled over certain bronze objects about 3 inches in length, which consist of two rigid rings united by a short band, from which three spurs project. These may be found in collections of Etruscan, Roman, and Greek antiquities in museums, where they are usually labelled as bow-pullers. Mr. E. S. Morse, the Director of the Peabody Academy of Science, has been interested for seven years in these problematical objects, and now carefully describes and figures a number of them in the *Bulletin of the Essex Institute* (vol. xxvi., 1894, p. 141). Some ten purposes have been suggested for their use; as a practical archer the author dismisses the bow-puller hypothesis, and, indeed, he says he must "reluctantly yield the solving of the enigma to others, having got no nearer an explanation of it than when I first began." Perhaps the most plausible view is that it may have been bound to the band to enable a chariot driver to hold the reins more firmly in driving.

DR. F. TETZNER concludes in *Globus* (Band lxx. Nr. 18) his series of four articles on the ethnography of the Kaschuben of the Leba Sea, in North-west Pomerania. The Kaschuben are the last Slavonic remnants of the Pomeranians in this district. He gives an interesting account of the folk-lore of this remote people, including some folk-songs, rhymes on grave-stones, and a few verses of children's singing-games, among which is the widely-spread "Ringel, ringel Rosenkranz"; but poor though the Kaschuben are in songs, they are rich in traditions and folk-tales. "Stupid Hans," who is so popular in German, Slavonic, and Lithuanian tales, plays the chief part in their märchen and narratives. Another important incident is "The Cheated Devil"; "The Wild Huntsman" comes next in popularity to the Devil as every one has seen him. The articles conclude with sections on manners and customs and festivals.

FROM the concluding summary of the paper on "First Records of British Flowering Plants," in the *Journal of Botany*, it appears that, of the 1440 species now reckoned as British, 510

have been discovered within the last two centuries, since the time of Ray. The earliest records are by Turner, 1538–1568, who seems to have known about 230 species; by Ray's time this had been increased to 725; and he brought the number of British flowering plants up to 930.

AN interesting fact in connection with the Schwendenerian theory that lichens are compound organisms consisting of an algal and a fungal constituent, which carry on a mutually symbiotic existence, is contributed to *Le Botaniste* in a paper by M. P. A. Dangeard. He states that a common and destructive disease of the Lombardy poplar in Italy is caused by a species of *Calicium* which he finds on the living branches, and which he names *C. populneum*. The genus is usually placed among the lichens; but this species is a pure fungus, destitute of any algal constituent, and carries on a parasitic life on the living tissues of the host.

A VERY remarkable degradation of the ovule takes place in some genera of parasitic plants, and is especially described by M. P. van Tieghem in a paper in the *Bulletin* of the Botanical Society of France, in the case of some Balanophoraceæ and Loranthaceæ. In one section of the former order there is in each carpel a single hypodermal endosperm-mother-cell which becomes the embryo-sac. A similar phenomenon occurs in *Arceuthobium* among Loranthaceæ, where two endosperm-mother-cells are produced at opposite sides of the ovarian cavity, and where, therefore, there is a placenta, but no ovules. In *Balanophora* the reduction is carried still further; the monocarpellary ovary produces beneath the epiderm a single endosperm-mother-cell; there is, therefore, here neither ovule nor placenta. This reduction of the ovule is frequently accompanied, especially in certain genera of Loranthaceæ and Balanophoraceæ, by a peculiarity in the mode of impregnation, which van Tieghem terms (in a paper in Morot's *Journal de Botanique*) *basigamous*, in contrast to the usual acrogamous mode. The ordinary position of the "egg-apparatus" or embryonic vesicles and of the antipodals is here reversed, the former being located at the lower, the latter at the upper end of the endosperm-mother-cell. This fact seems to confirm the theory that there is no physiological difference between embryonic vesicles and antipodals, except that the former are usually active, the latter inactive.

THE Austrian Meteorological Society has published an index to the first twenty volumes of its *Zeitschrift*. The work has been prepared by Dr. S. Kostlivy in a very careful manner as a mixed author and subject catalogue, arranged alphabetically. It is well known that the *Zeitschrift*, which was edited by the late Dr. Jelinek and by Dr. J. Hann, is a complete repertorium of climatology and terrestrial magnetism for all parts of the globe. This handy index, referring to the years 1866–85, will therefore be a boon to scientific men who may wish to obtain the results of observations made in any particular locality, without the trouble of referring to, and reducing the original records.

THE Meteorological Observatory of Upsala has published a series of concise tables for photogrammetric measurements of clouds. The usual calculations for determining the height of clouds are always tedious, especially when the photogrammetric method is employed, which, although it renders much greater precision possible than direct methods without photography, introduces fresh corrections and reductions. The tables in question, which have been calculated by Mr. J. Westman, will be found useful for the solution of the trigonometrical values of the cloud measurements which are now being specially made in various countries, in accordance with the wish expressed at the Meteorological Conference at Munich.

MR. W. F. CLAY, of Edinburgh, has sent u a copy of a new and enlarged reference list (No. 80) of books and memoirs on chemistry and the physical sciences generally. Individuals or institutions desiring to add important works to their librarie should procure a copy of Mr. Clay's catalogue.

THE following are the arrangements for lectures at the Royal Victoria Hall, Waterloo-road, S.E., during January, on Tuesday evenings, at 8.30:—January 5, Prof. H. G. Seeley, F.R.S., on the heat of the earth; January 12, Mr. A. Smith Woodward, on Syria and the Syrians; January 19, Mr. A. E. Tutton, on the glaciers and snowfields of the higher Alps.

WE have received the *Papers and Proceedings* of the Royal Society of Tasmania for 1894-95. The volume contains some interesting historical papers: one on the deportation of the Norfolk Islanders to the Derwent in 1808, by J. B. Walker; another on a MS. chart in the British Museum, showing Tasman's tracks in the voyage of 1642–44, by A. Mault; and a third, on early voyages to Papua in 1511 and 1545, by J. R. McClymont. A large number of field observations in botany, geology, zoology and ornithology are put on record, and Mr. H. C. Kingsmill gives an account of meridian observations with the Hobart transit instruments. The Society is largely interested in Antarctic exploration, and in the extension of the Australian meteorological service.

AN important addition to the synthetical methods for the preparation of carboxylic acids has been made by Messrs. Bredt and Kallen, whose work is recorded in the last instalment of the *Annalen*. They have found that unsaturated acids which contain two negative radicles united with one of the unsaturated carbon atoms readily unite with the elements of hydrocyanic acid, when the corresponding ethereal salt is boiled with a solution of potassium cyanide in dilute alcohol. Ethyl benzylidenemalonate, for example, which is formed by the condensation of benzaldehyde with malonic ether, is thus converted, with the loss of a carboxyl-group, into ethyl *β*-phenyl-cyanopropionate, $C_6H_5.CH(CN).CH_2.COOC_2H_5$, from which phenylsuccinic acid can easily be prepared. Certain unsaturated lactones, such as coumarin, also readily unite with hydrocyanic acid in this way, and there can be little doubt that the new reaction will prove of immense importance in the development of our knowledge of the carboxylic acids.

OWING to the fact that lithium is the only substance with which nitrogen will directly combine at ordinary temperatures, considerable interest attaches to the properties of the compound thus formed, lithium nitride. This compound, as M. Guntz showed some months since, is easily prepared by the combustion of lithium in nitrogen gas, and the specimen thus obtained was regarded as pure, since the nitrogen absorbed corresponded almost exactly with that required by the formula Li_3N. But in spite of this coincidence M. Guntz now shows that the product is not pure, as at the moment of combination the lithium attacks the boat in which it is held, although it is difficult to say exactly in what form the metal goes into solution in the molten nitride. Thus working with iron boats, the nitride contained from 2 to 8 per cent. of iron, and nickel is even more strongly attacked. Silver, platinum, quartz, and graphitic carbon were all tried, and found to be even less suitable than iron. Measurements of the molecular heat of formation of the nitride gave a value of 49·5 calories, or less than the value for the equivalent quantity of lithium hydride (65 calories). From this the conclusion was drawn that hydrogen ought to decompose the nitride of lithium with formation of the hydride, and this was found to be the case. The reaction, however, can be reversed, since at a high temperature a stream of nitrogen converts the hydride into the nitride.

THE additions to the Zoological Society's Gardens during the past week include a Golden Eagle (*Aquila chrysaetus*) from Norway, presented by Lord William Beresford, V.C.; a Raven (*Corvus corax*), British, presented by Mr. J. Collingham; two Tree Frogs (*Hyla arborea*), European, presented by Master Kneeshaw; a Grey Parrot (*Psittacus erithacus*) from West Africa, deposited.

OUR ASTRONOMICAL COLUMN.

COMET PERRINE (DEC. 8).—In *Astronomischen Nachrichten* (No. 3391) are given the elements and an ephemeris of the comet which was discovered by Mr. Perrine on December 8 last. This shows that the comet is decreasing in declination and increasing in right ascension, its position for December 30 being given as R.A. (apparent) 3h. 9·7m., Decl. (apparent) − 0° 9′. Its brightness is now about half what it was on December 10. The elements, communicated also by Dr. F. Ristenpart, are very nearly similar to those referred to above. These are given in a later number of the *Astronomischen Nachrichten* (No. 3393), together with an ephemeris, calculated by Dr. Ristenpart, up to the middle of January, from which we make the following extract:—

12*h*. *Berlin M.T.*

1897.	R.A. 1897·0 h. m. s.	Decl. 1897·0 ° ′	*s*	log *r*.	log. Δ.	Br.
Jan. 1 ...	3 28 11	... − 0 49·1				
2 ...	33 28	... 0 56·7				
3 ...	38 38	... 1 3·5	...	0·1030	9·6149	0·46
4 ...	43 41	... 1 9·5				
5 ...	48 36	... 1 14·7				
6 ...	53 24	... 1 19·2				
7 ...	58 5	... 1 22·9	...	0·1123	9·6482	0·38
8 ...	4 2 38	... 1 26·0				
9 ...	7 5	... 1 28·4				
10 ...	11 25	... 1 30·2				
11 ...	15 39	... 1 31·4	...	0·1222	9·6823	0·31
12 ...	19 48	... 1 32·0				
13 ...	23 52	... 1 32·1				
14 ...	4 27 46	... − 1 31·6				

A matter of some interest is the similarity of the elements which have been obtained by Messrs. Hussey and Perrine, and those of Biela's comet. The following shows the two systems of elements:—

	Perrine.	*Biela* 1832 *III.*
T =	1896, Nov. 25·67 M.T.G.	1832, Nov. 26·4 M.T.G.
ω =	164 36	109 56
Ω =	243 49	248 12
i =	16 29	13 12
q =	1·1540	0·8793

"HIMMEL UND ERDE."—The astronomical contributions to the December number of this monthly include, besides a somewhat lengthy obituary notice of M. Tisserand (with a portrait), the last of a series of articles by Dr. G. Witt on the planet Saturn, several illustrations accompanying the text; such recent work as that accomplished by Keeler regarding the constitution of the ring as deduced from the movement of the lines in the spectrum, and Campbell's spectroscopic work are both referred to at some length. Of the shorter articles, an interesting account is given of Prof. Newcomb's important work on the transits of Mercury across the sun's disc. By using newly-constructed sun- and Mercury-tables, Prof. Newcomb still found that differences between calculated and observed values were obtained. How to account for these was his next object of research. Might not such differences be due to a false assumption in assuming that the earth rotates at a constant speed around its axis? Or are they the results of inequalities in the moon's motion? Prof. Newcomb finally concluded that in the mean motion of the moon there must be one, if not more inequalities of long period which our present theory has not yet analytically proved.

ASTRONOMICAL SOCIETY OF FRANCE.—The *Bulletin* of this Society for the month of December contains, among other matters, an interesting address by M. Janssen on the late Director of the Paris Observatory, M. Tisserand. M. Gilbert concludes in this number his article on the mechanical proofs of the rotation of the earth, dealing here chiefly with the experiments made with various kinds of gyroscopes. Among the notes will be found a description, by M. Camille Flammarion, of a pulpit sculptured in wood, having the form of an inclined terrestrial globe with the continental outlines worked on it. The south pole is situated underneath, and bears the inscription, "Regiones australes incognitæ." It was constructed in the year 1600, and is cut out of a single piece of oak. M. Flammarion discovered this pulpit in the Chapel of Saint-Sang at Bruges, a small church built in the year 1150, and restored in the sixteenth century and since.

THE DAVY-FARADAY RESEARCH LABORATORY.

THE Davy-Faraday Research Laboratory, established and equipped by Dr. Ludwig Mond, was opened by the Prince of Wales on Tuesday, December 22. We have already expressed our appreciation of this generous gift to British science, and have described the accommodation and equipment of the new laboratories (vol. liv. p. 200). With a munificence which we hope will find many imitators, and a just regard of the value of scientific research, Dr. Mond has established a place where investigations can be carried on without interruption, and with the best appliances. He has not only furnished the laboratory with the most modern instruments and appliances for researches in pure and physical chemistry, but has also given an ample endowment, so that the laboratory may be maintained in a state of thorough efficiency, his object being to give every assistance and encouragement, within the limits of the endowments, to scientific workers. To accomplish this has cost a hundred thousand pounds, of which sum 38,000*l*. is sunk in the building and its equipment, while the remaining 62,000*l*. constitutes the endowment fund. For the very practical way in which Dr. Mond has shown his interest in the promotion of material knowledge, men of science cannot express too warm a sense of gratitude. We look to the workers in the laboratory to repay the generosity of the founder by their contributions to knowledge, and so induce other benefactors to follow the example set by Dr. Mond.

The following account of the opening of the laboratory, abridged from the report in the *Times*, will be read with interest:—

Dr. Mond, addressing the Prince of Wales, said that under the auspices of his Royal Highness's august father, whose enlightened mind had fully realised that the pursuit of pure science was the most potent factor in the promotion of the intellectual as well as the material progress of this or any other nation or of humanity at large, a movement was set on foot fifty years ago to found an institute for the pursuit of pure chemistry, which was not only to give practical and systematic instruction to students, but was also to provide a place where original research could be conducted by fully-qualified investigators. At first it was proposed to attach this institute to the Royal Institution. The eminent professors of the time, Faraday and Brande, expressed their strong approval of the intended project, and their desire that it might be carried out at the Royal Institution, if it could be done well; but, nevertheless, this idea had to be abandoned, because sufficient accommodation could not be found within the precincts of the institution. The first part of the scheme was carried out a few years later by the foundation of the Royal College of Chemistry, which, under the guidance of the illustrious Hofmann, soon became one of the most successful schools of chemistry in the world; but the second part, that of providing a place where original researches could be carried on by a number of independent investigators, had been waiting all this time for its realisation. Several years before these facts came to his knowledge he had determined of his own accord to found in London a laboratory of research in purely scientific chemistry and in physical chemistry, that borderland between chemistry and physics from which, in his opinion, they might hope to learn more about the real nature of things than from any other branch of natural science. He also had come to the conclusion that such a laboratory would derive the greatest advantage if it could be associated with the Royal Institution of Great Britain, which had during its long existence made the promotion of original research in these sciences one of its main objects, and the laboratories of which had been productive and

were still productive of such marvellous results at the hands of the eminent professors elected by the institution. He therefore gladly embraced the opportunity which recently presented itself of acquiring the commodious house immediately adjoining the Royal Institution, and submitted a scheme to its managers, which met with their fullest sympathy and which they readily accepted with unanimity. Work was immediately commenced to alter the building so as to make it suitable for its new purpose, and, thanks to the advice which had been freely extended to him by scientific men all over the world, and the active co-operation of Lord Rayleigh and Prof. Dewar, of the architect, Mr. Flockhart, and of his son, Mr. Robert Mond, to whom he left the selection of the apparatus and the equipment of the place generally, the laboratory which they asked his Royal Highness to inaugurate that day would stand favourable comparison with any other laboratory in or out of England as to the completeness and convenience of its appliances, and was provided with the best instruments made at the present day. It was unique of its kind, being the only public laboratory in the world solely devoted to research in pure science. In order to insure its continued usefulness he had endowed it so as to cover the cost of maintenance of the fabric and all necessary current expenses. He named it the Davy-Faraday Research Laboratory in perpetual memory of those two great pioneers of science who carried out their world-famed and epoch-making researches almost on that spot, and whose example he hoped would stimulate and inspire every one who came to work under that roof. It was a source of very great gratification to him that the eminent successors of those great men, Lord Rayleigh and Prof. Dewar, had consented to undertake the duties of directors of the laboratory, and this gratification had been the greater because those gentlemen made it a condition of their acceptance of the post that it should be without emolument. An experienced superintendent had been appointed in the person of Dr. Scott, and nothing was now wanting for its success but a number of investigators competent and ardent to continue the great work of this century, the unravelling of the secrets of nature. As soon as his Royal Highness had declared the building open, persons of either sex or any nationality would be welcome within its walls who could satisfy the laboratory committee that they were fully qualified to undertake original scientific research in pure and physical chemistry, and preference would naturally be given to those who had already published original work. If this country had distinguished itself in one way more than another in that glorious rivalry with other nations for extending our knowledge of natural phenomena and our power over the forces of nature it had been by the large number of contributors to our knowledge, who on the continent would be called amateurs in science—men who devoted their lives to the study and advancement of science from pure love for the subject. He need only instance the names of Cavendish, Joule, and Darwin to say that they included men of the very highest rank. In giving this laboratory to the English nation he had done so in the firm conviction that this country would continue to bring forth in the future, as it had done in the past, men of the same rank and of the same devotion to science for its own sake, and it was a fond hope of his that such men would find there all the facilities and all the necessary appliances for carrying out their researches. The further we advanced in the study of nature the more accurate and elaborate was the apparatus required, and the more difficult it became to carry on delicate work in a private laboratory. He had placed that laboratory in the centre of London because he believed that this great city would continue to be the intellectual centre of the civilised world, where the brightest minds would congregate. He had intrusted it to the Royal Institution so as to insure its being open to men and women of all schools and of all views on scientific questions. It had given him great pleasure that in establishing the Davy-Faraday Laboratory, he had been able at the same time to enlarge the old laboratories of the Royal Institution, and also to make additions to its library and reception rooms, which he hoped would prove a convenience to its members. He looked upon that laboratory as an important step forward in that great movement for the advancement of scientific research in this country, to which his Royal Highness's revered and illustrious father gave so powerful an impulse, and which has been so distinguished a feature of the many-sided and unparalleled progress made by this nation during the glorious reign of his mother, her Majesty the Queen. It was a source of specially great satisfaction to him that his Royal Highness deemed that laboratory worthy to be opened by himself, and he humbly thanked his Royal Highness for having come there that day. His presence on that occasion would certainly add very greatly to the success of the Davy-Faraday Research Laboratory of the Royal Institution.

The Prince of Wales in reply said:—Prof. Mond, it affords me much satisfaction to assist at the opening of the series of beautifully-arranged and well-equipped research laboratories which this country owes to your generosity, and I congratulate the members of the Royal Institution of Great Britain upon this most important accession to the resources which have been placed at the command of the institution for the advancement of chemical and physical science. The Royal Institution has long enjoyed a world-wide reputation, thanks to the marvellous work of the succession of illustrious men whose researches, carried on within these walls, have very largely contributed to secure and maintain for this country a foremost position as a source of great discoveries and important advances in science and its applications. The identification of the laboratories which you have founded with the names of two of the most eminent of former professors of the Royal Institution and of English men of science—Humphry Davy and Michael Faraday—is a graceful act on your part. The fact that the present distinguished professors of physics and chemistry, Lord Rayleigh and Prof. Dewar, have undertaken the important duties of directors of the new research laboratories without any remuneration must afford most gratifying evidence to you of the great faith entertained by them in the benefit to the promotion of science which your wisely-applied munificence is destined to realise.

THE BACTERIA WHICH WE BREATHE, EAT, AND DRINK.[1]

THE surface of the earth is inhabited by bacteria: wherever there is dead organic matter, wherever there are human or animal excreta, wherever decomposition is going on, in stagnating or in flowing water, within our houses and without, bacteria collect. They are so widely distributed that practically everywhere we are surrounded by these minute vegetable cells. From the bacteriological standpoint we live amongst decomposing matter. Without bacteria there is no decomposition or putrefaction; they reduce the organic matter to "dust," and with the atomised matter they are again carried away by air or water. Dust is laden with bacteria, and since a great part of dust is derived from decomposing matter, it follows that, although we do not realise it, we are living in an atmosphere of decomposition.

The air which we breathe, therefore, contains bacteria. These vary in amount with certain conditions. If the air is calm their number diminishes, but if there is wind or draught, they may be present in enormous numbers. Again, in the open country air there are, other things being equal, considerably less micro-organisms than in the dusty streets of London. Thus there is an extraordinary difference between the air in Oxford Street and on Wandsworth Common.

The air may be roughly tested by coating sterile plates of glass with gelatine, and exposing them for a given time in the locality which we wish to examine. The bacteria will fall on the surface of the gelatine, and on incubation at a suitable temperature they will develop into visible colonies which can be readily counted. The number of colonies is a fair, though not an absolute, index of the bacterial purity or impurity of the air. The more colonies we find on the surface of the gelatine, the more bacteria, of course, the air must have contained. A plate exposed in Oxford Street would be covered with colonies, while a plate exposed on Wandsworth Common would show only a few. This is, of course, only a rough-and-ready method which cannot be used for accurate work, but, nevertheless, it gives us good comparative results.

The lantern slides exhibited on the screen demonstrate to you that the air which we breathe always contains micro-organisms, and that therefore we are always inhaling bacteria. Many organisms are incapable of growing at the temperature of the body; they require a lower temperature. Such organisms, we may assume, cannot thrive in the body of the warm-blooded animal,

[1] A lecture delivered at the London Institution, by Dr. A. A. Kanthack Lecturer on Pathology, St. Bartholomew's Hospital.

and are therefore, probably, of little importance so far as we are concerned. Keeping this in view, I have always incubated my plates coated with agar-agar at the body temperature, in order to gain information as to the approximate number of organisms which are likely to find access to our respiratory tract, and which have a chance of thriving there. I have not attempted to separate the aerobic organisms from the anaerobic ones, *i.e.* those which can grow in the presence of oxygen from those which cannot. All I wish to show is that under ordinary conditions of life we must breathe an air which contains bacteria, sometimes many bacteria. These plates do not tell us how many bacteria we inhale in a given time; they simply tell us that the air which we breathe is not sterile.

The bacterial flora of air varies considerably. The lady shopping in Oxford Street will inhale more bacteria than the boy who runs about on Wandsworth Common.

We all expect to find that the air in a railway carriage of the Underground Railway is full of bacteria; but, although very rich in bacteria, it is not so impure as might have been anticipated.

I have prepared a number of plates from the air in my laboratory, exposing them from one to five minutes. Some of them are very full of colonies, others less; and this depends on the number of students that have been at work during that time. The more students the more dust, and therefore the more bacteria.

Wherever many people are congregated the air becomes laden with dust and bacteria. Thus plates exposed in the Surgery of one of our largest general hospitals for three to five minutes are covered with numerous colonies. Compare this with the air in the quadrangle of the same hospital, and you will see the effect of confinement and of crowding together. In the former case we find numerous colonies, while in the latter case—*i.e.* in the quadrangle—the air is much freer from micro-organisms. This is also shown by plates taken from the Apothecary's Shop of the same hospital during a time when the patients collect to obtain their medicines; here the air is laden with bacteria.

If you desire a further example, you will find it in plates prepared in the Smithfield meat-market. After a minute's exposure already they are covered with colonies; and we cannot wonder at this, if we remember how active the life there is, and how much organic matter is carried about.

In foggy or misty weather, when the air is quiet, the number of organisms is greatly reduced. It requires, therefore, but little reflection to recognise that, under ordinary conditions, the air which we breathe contains numerous bacteria: we live in a world which is not sterile, and, therefore, unless there exist special preventive measures, those body cavities which are in direct communication with the outer world must also contain bacteria. The mouth, the alimentary and respiratory tracts, and the pores of our skin are all in direct communication with space outside us, in fact, from the bacteriological point of view they represent simply the outer world.

We may, therefore, expect that the organisms which exist outside, in part at least, also find their way into these body spaces or cavities, even if they were not carried into the mouth with our food, or into the nose by the process of respiration. We cannot possibly prevent the bacteria from entering the mouth, even if we refused any but sterilised food. This is an important point to remember, because it proves the impossibility of excluding bacteria from the digestive tract. Saliva always contains them, often in great numbers; and as saliva is constantly swallowed, they must find their way into the stomach. But to return to the bacteria which we breathe. The air passages, *i.e.* the nose, larynx, trachea, bronchi, and their ramifications, and the alveoli or air spaces of the lungs contain bacteria. In normal respiration the inspired air enters the nose, but the anatomical structure of the latter is such as to act as a bacterial filter, imperfect no doubt, but still capable of retaining from three-fourths to four-fifths of the bacteria of the inspired air. Therefore, although large numbers of bacteria find their way into the nasal cavities, the true mucous membrane of the nose is surprisingly poor in bacteria; and this to some extent is due to filtration, and to the fact that healthy nasal mucus possesses considerable bactericidal or disinfecting power. If, however, the nasal mucous membrane is diseased, and it is frequently diseased in this country, large numbers of organisms may be found. The nose, therefore, is an important bacterial filter, and it follows that breathing through the nose is the best method which the body possesses for the purification of the air which we breathe. When we are forced to breathe through the mouth, bacteria are readily inhaled into the larynx. The latter, as well as the trachea, bronchi, and lungs in man always contain bacteria, because the nose is a very imperfect filter which often gets out of order, and also because the respiratory tract is in direct communication with the outer world. It is stated that the trachea, bronchi, and lungs of animals (rabbits) are almost free from bacteria; it is certainly not so in man.

The air which we breathe contains both organisms which are capable of producing disease, and organisms which are harmless. The latter are far more numerous; still pathogenic organisms, *i.e.* disease-producing organisms, do float about in the air, and may then be inhaled. The organisms which we find in the nose, mouth, larynx, and lung include some undoubtedly pathogenic forms, as for instance the micro-organisms of pneumonia, suppuration, &c. These exist in space around us, and therefore, unless they are destroyed in the respiratory passages, they must find their way into the cavities of the body which are in direct communication with the outer world: and thus we see that virulent organisms may enter the body and remain there without causing any lesions, for although we frequently inhale pathogenic organisms we do not inhale the diseases which they are capable of producing. The bacteria enter the body, but not its tissues; they thrive in the secretions and on the mucous membranes lining the various cavities of the body. But that only means that they are practically still outside the body proper. It is a common error to say that because an organism is found inside some space or cavity of the human body, that therefore it lives in the tissues or in the body. As I said before, all the cavities and spaces in direct communication with the outer world are the outer world, and we may expect in them the same organisms as occur in the outer world. The resistance of our tissues in health, and the absence of predisposing influences prevent the pathogenic organisms present from doing more than leading a harmless or saprophytic existence; but if for some reason or another they actually enter or irritate the tissues, the most serious forms of disease may appear, as for instance pneumonia. Many of us carry the organism of this disease about in our mouths, bronchioles or alveoli, although we remain perfectly healthy; pneumonia, however, frequently appears after a drenching or a chill. The coccus of pneumonia, which lay harmlessly on the mucous membrane, now assumes a virulent character, invades the lung tissues, and in some cases even the circulation. The bacillus of tuberculosis in rare cases has also been found in the nasal mucous membrane of individuals attending on consumptives; it did, however, no harm so long as it was outside the tissues on the mucous membrane, *i.e.* in the outer world whence it had come.

Anyhow, we must recognise that since, under ordinary conditions, we live amongst bacteria and decomposing matter, we must be inhaling large numbers of bacteria into our nose, mouth, larynx, trachea, bronchi and lungs; and that since pathogenic bacteria from time to time occur in dust, these also must find their way into those spaces and tracts. But we need not feel alarmed and insist on a sterile supply of air, because the danger of aerial infection is but slight, and because the survivors amongst the inhaled micro-organisms will remain harmless, unless the system is weakened or rudely disturbed by some interference. It is, however, well to remember that our respiratory passages may, and generally, perhaps, do contain numerous germs capable of producing disease and death, and that these germs may lie dormant there for a long time, ready under provocation to do their worst.

There is one other organism I wish to single out, because I shall have much to say about it subsequently, that is the *Bacterium coli commune*. This organism I have always found in saliva and in sputum, on the tonsils and on the pharynx. It is an ubiquitous organism outside the human body, and therefore occurs in the body spaces and, especially, in the intestines which are continuous with the outer world; and it would be surprising if it did not.

We may here conveniently consider the flora of the mouth and pharynx. Whatever micro-organisms are present in the mouth must have got there from the air or the food. At a particular moment there may be an enormous number of organisms present, but many of them are merely temporary visitors; they either die because they do not find suitable conditions, or they are passed on into the stomach and intestines.

The mouth is not guarded by a filter like the nose, but to a slight extent at least the saliva possesses disinfectant properties. The oral cavity is, however, never free from microbes, and some of them belong to highly pathogenic species, as *e.g.* the coccus of pneumonia, several forms of pus producing micro-organisms; and the diphtheria bacillus has occasionally been detected in the mouth or on the tonsils without there having been any history of direct contact with diphtheria cases.

These organisms may lead a saprophytic existence, and may remain harmless for a long time, till for some reason or another they are awakened to a life of virulent activity. Mr. Stephens and I have frequently found bacilli resembling the diphtheria bacillus in the dust, and though some of them are certainly not true diphtheria bacilli, others must be regarded with suspicion. Personally, after prolonged observations which I have carried on with Mr. Stephens at St. Bartholomew's Hospital, I incline towards the view that the diphtheria bacillus is more widely distributed in space than is generally believed, and that in a harmless or saprophytic condition it may be inhaled and fix itself upon the tonsils.

We have found in the air and on the surface of the body several varieties of bacilli, morphologically identical with the diphtheria bacillus. These are generally called pseudo-diphtheria bacilli. They are widely distributed. Some of them are so different in their biological characters from the diphtheria bacillus that they may be put on one side; others, however, so closely resemble it that they cannot be treated with the same contempt. Some observers feel a peculiar satisfaction in hiding themselves behind the security of the pseudo-diphtheria bacillus, which is an undefined quantity, including many varieties of forms. No one nowadays ventures to define the cholera germ; there are too many varieties of it. We believe that caution is advisable in the diagnosis of the diphtheria bacillus. We have come to the conclusion that when a bacillus is morphologically identical in appearance with the diphtheria bacillus, and in its biological characters closely resembles the conventional type of the diphtheria bacillus, he must be a bold man who ventures to say off-hand that this bacillus is or is not a diphtheria bacillus. We know of no test-tube reaction or animal experiment which will always decide it. We believe that the diphtheria bacillus is found in nature as a saprophyte, and that under special conditions it becomes pathogenic, and then diphtheria results. We see once more, that in the mouth also pathogenic organisms may enjoy a harmless or non-pathogenic existence, until conditions arise which alter their character and render them virulent.

We shall now pass on to a consideration of the bacteria which we eat and drink.

That severe gastric and enteric lesions and derangements, often accompanied by the most severe symptoms, and occasionally followed even by death, are only too frequently the result of consuming unsound food, cannot be questioned; and from the hygienic standpoint we must insist upon the sale of proper and sound food, and upon a careful preparation of food. "Food poisoning" may be due:—

(1) To irritation, the food being good in itself, but indigestible or altogether unsuitable.

(2) To bacterial infection; or

(3) To intoxication with poisons elaborated in the food.

(4) To intoxication by poisons purposely or accidentally added to the food.

Unfortunately, if we except the last cause of "food-poisoning," we have no sure tests which we can readily apply to gain information whether disease lurks in a tempting dish. We generally raise the cry of "death in the pot" after the mischief is done, and as a rule we do not get much further. In a free and easy manner the analyst and the medical officer of health speak of ptomaines and toxines which they generally fail to detect, or it is stated that an appallingly large number of microbes have been found in the fatal dish—and this is often considered sufficient evidence to explain the distressing symptoms which ensued.

The first point which I wish to make clear—or you may say to obscure—is the value of the quantitative bacteriological examination in cases of food-poisoning.

In many reports we read that an unusually large number of bacteria were found, and that amongst these were various forms of the *Bacterium coli commune* or of *Proteus*. Now all such reports are somewhat unsatisfactory, unless we also know more of the circumstances under which the food was prepared or preserved.

First, as to numbers: what do they signify? Because we find 500,000 to a million, or even innumerable micro-organisms in a c.c. of fluid or in a minute particle of solid, can we, therefore, always say, in the absence of other evidence, that as food such articles are unsound, and that such numbers account for the symptoms observed? I think not, because I can quote figures which prove that persons who never suffer or have suffered from food-poisoning habitually ingest enormous quantities of bacteria without any evil accruing therefrom.

(1) *Milk* is constantly consumed by many individuals without harm. Now the best samples of milk that I ever obtained in London contained 250,000 micro-organisms per c.c.; generally we find 1 to 2½ millions per c.c., and if we let it stand at the ordinary temperature of the room these numbers may increase 20 to 1000-fold. Yet such milk is generally harmless, and we are not justified in condemning it on account of the large number of germs present. It is impossible to obtain milk free from bacteria, even if the cows were to be milked in a modern operating theatre, because the ducts in the teats always contain micro-organisms, which are washed into vessels, and there quickly multiply, and during the necessary exposure which must follow, more organisms find access to the milk. Mr. Parfitt has recently made some careful examinations of the bacteria present in London milk in my laboratory, and has found that 1 c.c. of milk contained 1,250,000 microbes, of which 303,000 were capable of growing at the temperature of the human body. I would, therefore, not undertake to condemn milk unconditionally, because 1 c.c. of it contained 500,000 to one million germs, and would hesitate to do so if it contained two, or even twenty, millions. Numbers here are not a true criterion; hundreds and thousands of people consume milk teeming with bacteria. I do not say that there is no danger in milk, for we know that tuberculosis, enteritis, diphtheria, and scarlet or typhoid fever have often been traced to milk; nor do I mean to say that the process of collecting and dealing with the milk could not be improved. These points are beyond our present argument. All I wish to show is that most of us consume habitually a large number of organisms without feeling any the worse for it. I do not recommend a bacterial diet, but I merely state the fact that we consume an enormous quantity of bacteria.

I know very well that milk is a frequent cause of enteritis in children, especially during the hot summer months, and this affection, which destroys the lives of many infants, is undoubtedly frequently due to bacteria present in the milk. Prof. Flügge's experiments have practically settled this point, and we must agree that under certain conditions a considerable accumulation of bacteria in the alimentary tract can hardly be a matter of indifference. It is, however, difficult to say what the limit is, beyond which the ingestion of micro-organisms becomes dangerous; and again it is possible, nay probable, that in many cases, for some reason or another, conditions arise which allow organisms existing in the gut, such as the *B. coli*, to proliferate at a great rate, and thus to produce most serious symptoms and intoxications. It is right and proper to avoid all dangers and risks by collecting and preparing food properly, by cooking it sufficiently, and by consuming no food that has been kept too long; but it is equally right and proper to remember that some articles of food are not only consumed, but also relished, which are known to contain enormous numbers of micro-organisms. We cannot make our lives miserable by refusing all but sterilised food; and I wish to point out to you that some articles of food which we particularly enjoy are teeming with bacteria, and for all that are not to be condemned. The question is, how did the organisms find their way into the food, *i.e.* what are the causes and circumstances of the contamination?

We are everywhere surrounded by danger, so far as bacterial infections are concerned. A slight scratch or a fall on the ground may be the cause of lock-jaw or tetanus. Are we, therefore, to give up all forms of exercise, such as football and bicycling? The friendly services of the bacteria outweigh the injuries which they inflict upon us, and I believe that just as in the world around us they do us many a good turn, so also in the world within us do they assist us. Possibly we could get on without them, but we do not know yet whether we could get on better without them than with them. Let us fight our foes, such as the organisms of typhoid fever and cholera; but this can be done with coolness and common-sense, and insistence on cleanliness and ordinary precautions.

(2) All *cold meat* contains numbers of organisms enough to frighten timid people. These are most numerous on the outside of the meat, but the interior is by no means free from them. I have frequently examined cold meat, and a single platinum loop often carries away innumerable germs from the superficial parts, and yet, as a rule, no ill-results ensue from the consumption of cold meat as ordinarily prepared. It is the custom to declare with disgust the legions of micro-organisms found in potted meat or in cold meat-pies, suspected as the cause of food-poisoning, and yet we find that potted meat and sandwiches bought at the most fashionable restaurants of London possess a flora which almost rivals the most virulent potted meat or veal-pie, and which, if numbers were an absolute test, should prostrate any one partaking of them. An error which is often committed, is that articles of food which bear the stamp of respectability, and which the better class consume, are not examined, so that we remain ignorant as to the numbers of organisms ingested with food acknowledged to be sound. I have recently examined the sandwiches offered for sale at one of the best-known London restaurants, and I find that less than a millionth part of a sandwich examined generally contained innumerable micro-organisms. I have myself eaten four to six sandwiches at that restaurant every day for the last twelve months or so that I spent in town, and live to tell the tale, nor have I ever heard of any one coming to grief from the effects of those sandwiches. Similarly potted meat, bought at the best sources, contains an extremely large number of micro-organisms, both aerobic and anaerobic.

(3) If we fix our attention upon the food of those who care for "good things," we find that *oysters* and cold *game* are also thoroughly impregnated with bacteria, yet, in spite of a few accidents, and in spite of the aspersions cast upon oysters, no one, I think, would venture to declare these articles to be invariably unsound food. Oysters are consumed by thousands of persons without bad effects, and they are often given to debilitated patients. We cannot, therefore, appeal to numbers as an absolute standard of good and bad food. However, we must insist upon this, that the oysters be cultivated and kept under conditions which exclude sewage contamination and filth. The layings should not be subjected to anything approaching risk of infection. Sewage always contains large numbers of *B. coli commune;* therefore, oysters, known to be fattened in sewage-polluted beds, which contain numerous *B. coli commune*, cannot possibly be said to be free from sewage contamination, if they have been properly and ably examined. If we are aware that direct contamination with human excreta has been avoided, we need not be alarmed at the presence of what might appear to be a large number of bacteria in oysters, so long as the latter are fresh. No one, after reading Dr. Thorne Thorne's masterly introduction to the recent Local Government Board Report on oyster culture in relation to disease, can doubt that the oyster may be the cause of disease, and that this danger can be obviated by removing the chances of sewage pollution. The chief danger arises from the possible presence of the typhoid bacillus, or the vibrio of Asiatic cholera. Their presence we must fear, but to restore a little confidence in the abused mollusc, I will quote some of Dr. Thorne Thorne's own words: "Only a few of the layings, fattening beds, or storage ponds round our coast can be regarded as theoretically free from every possible chance of sewage pollution. But, as regards the majority of them, any such polluting matter becomes mixed with so vast a bulk of water that it is difficult to see how the layings can be subjected to anything approaching substantial risk or deleterious influence." Still, as the reports show, there are exceptions to this comforting rule, and this should not be.

(4) What I have said about bacteria in normal food will become still clearer if I quote a few figures obtained by Mr. Stephens, when working in my laboratory on the bacteriology of *ice creams*. It has become the custom of using strong expressions against the ice creams sold by the Italian street vendor. It is indeed disgusting to see the same grimy glass used by a row of dirty boys, it being periodically washed in filthy water and wiped with an equally filthy rag; but in many quarters these ice creams have been condemned on account of their rich flora. Now I may remind ladies fond of ices, that the ices bought at the fashionable confectioners in London, as a rule contain as many bacteria as, if not a larger number than, the Italian's ice creams, on which they would look with disgust, if they regard them at all.

In several samples of street-ices Mr. Stephens found from 2 to 5 millions of bacteria per c.c., while strawberry ice creams bought at well-known West End confectioners at times contained from 10 to 14 million germs per c.c. The average number for the two kinds of ices was 7 millions per c.c.

If street-ices are to be condemned therefore—and there are many reasons why they must be condemned—we are not justified in condemning them on account of the number of bacteria contained in them, for in this respect they are no worse than the best ices sold in the West End of London, which afford great and generally harmless pleasure to many; but we must condemn them on account of the circumstances under which the bacteria have found their way into the Italian ice creams.

I could multiply instances to prove that most of us consume enormous numbers of bacteria. I have examined cakes and many other delicacies, and must come to the conclusion that the better-class people ingest as many, if not more, bacteria than those who from poverty are tempted to procure cheap and stale food. I must, however, content myself with the above statements, which prove the difficulty of deciding from a purely quantitative bacteriological examination of food articles whether, other things being absent, we are justified to express a categorical opinion as to their quality, safety, or nutrient value. In examining drinking water, the number of bacteria present in 1 c.c. is no doubt a measure of the adequacy of the filters, but one may wonder why 100 germs per c.c. should generally be considered the maximum number of bacteria which good potable water is allowed to contain. This or any other number absolutely measures the quality of the filter, but not the safety of the water.

We must now pass on to the second point, *i.e.* the species of micro-organisms present in sound food. Here again we find the results of bacteriological examination often unsatisfactory. We have but few, if any, organisms, so far as our present knowledge reaches, which are absolutely characteristic of unsound food, and which are invariably associated with it. In ordinary food I have always found numerous pathogenic or suspected organisms. The *B. coli commune*, *Proteus* forms, *staphylococci*, *streptococci*, organisms resembling the diphtheria bacillus, they may all be found in food which is considered to be above suspicion as well as in food which, by a process of exclusion, reasonably or unreasonably has laid itself open to doubt as to its integrity. I have frequently examined meat, suspected and unsuspected, and feel convinced of this, that in most cases from a qualitative examination we can only proceed to argue with caution, unless we succeed in separating the bacillus of tuberculosis, of anthrax, or of typhoid fever, the vibrio of Asiatic cholera, or probably one or other bacillus of enteritis. Various forms of *B. coli commune* and various forms of *Proteus* are common in articles of food, and were separated often in numbers in many of the sandwiches and other food articles examined. When they have been found in suspected articles in large numbers, they have frequently been considered as being adequately confirmatory of the suspicions aroused by the circumstances of the case. They are certainly evidence of staleness, and may become condemnatory evidence. For instance, water rich in *B. coli* derived from a river into which sewage flows, or into which excreta are drained, must be condemned, because this is clear evidence of sewage or fæcal contamination and of incomplete filtration. It has been thought that food containing large numbers of the *Proteus vulgaris* cannot be eaten with impunity. That is true in some and it may be in many cases, and is a good *post hoc* argument, but it cannot be made an absolute standard. In many sandwiches examined I have found large numbers of *Proteus*, and yet they proved harmless. This organism *per se* does not justify a verdict against the food. In milk the *Proteus* is extremely common, in most samples, at least, examined and consumed by myself without bad results. Now a writer in the *British Medical Journal* of 1895, having made the same observation, argues thus:—"Forms of *Proteus* are found in putrefying organic matter of all descriptions, and their distribution is wide. Their presence in milk must mean one of two things, either direct contamination with putrefying matter, or needless exposure to an atmosphere containing particles of decomposing matter." Thus this observer writes. *Proteus* is so common in food, because it is found everywhere in dust, and bacteriologically speaking all dust-laden air must contain particles of decomposing matter; hence the presence of *Proteus* may not mean more than ordinary exposure, not even needless exposure. It is difficult to see how one is to avoid the *Proteus*. Matter decomposes because the putrefying germs are present everywhere in dust, and putrefied matter rising as dust increases the stock of such germs in the

air; the vicious circle is at once established. It is difficult to say what number of *Proteus* bacilli in an otherwise sound article of food would signify danger, and the value of such statement depends on the experience of the observer and on the circumstances of the case. But as far as mere qualitative evidence goes, viewed from the bacteriological standpoint, we all live amongst particles of decomposing matter. Should we get almost pure cultures of *Proteus* or *B. coli* and these forms present in large numbers, matters are easy enough—such food must be condemned.

Let us now turn to the *Bacterium coli*. Water has been condemned because it contained this organism in small or large numbers, and the writer quoted above asserted that "the colon bacillus, if found in potable water, is usually taken as diagnostic of sewage contamination," and "its frequent presence in milk he derives from the soiled cow and its surroundings, and he regards it as *par excellence* diagnostic of fæcal contamination." Many writers believe that water which contains this microbe at all, in however small numbers, has in all probability been polluted with excremental matter, and they regard this bacillus by itself as typical and specific of fæcal matter.

Now I consider that the *B. coli*, in its various forms, is a rather abused organism. With Mr. Stephens I have worked at this organism since the beginning of 1894, and have separated it wherever I came across it. It is our experience that it occurs in some form or another almost anywhere and everywhere: in the air, in the soil, in the water, in dust, of course in varying and variable quantities. We have found it in the secretions of the body where direct intestinal contamination could be excluded. It occurs in normal saliva, in expectoration, whether of health or disease, not occasionally, but practically always. In diphtheritic membranes, in abscesses, in the skin—everywhere it is. Fluids and solids exposed to air contain it; nothing can avoid it. On the surface of meat, even frozen mutton, on bread, fruit—everywhere it may be found. A few hours after birth it has been found in the intestinal tract of infants. We, therefore, have come to the conclusion that the *B. coli* is present in the intestines, because it is ubiquitous outside the animal body, and not that its presence anywhere and in any number outside the digestive tract necessarily signifies direct filth contamination. No doubt animal excreta assist in keeping up its supply, but it seems to me that simply because this bacterium occurs somewhere or other, to speak of direct filth contamination without other existing evidence is not quite logical. Of course it may be said that since filth forms a great source of this bacterium, and since the alimentary tracts, so to speak, envelops the earth, that therefore the presence of the *B. coli commune* does prove such contamination; but then it comes to this, that from a bacteriological standpoint we live and breathe in decomposing matter. I therefore doubt whether we have any right to condemn apparently sound water or food which contains the *B. coli commune* on the assumption that it has been soiled unless we have real or circumstantial evidence of such soiling. If water contains a large number of *B. coli commune*, we may have to condemn it on the score of being insufficiently filtered if the source of such drinking-water contains the *B. coli commune*: but in the absence of other evidence we cannot always do that. The bacillus fluorescence is almost constantly found wherever the *B. coli* occurs, yet no one would regard its presence in water, even in large numbers, as absolute evidence of direct filth contamination. Yet the above observer concluded that the presence of the bacillus fluorescence in milk may be taken as presumptive evidence of added water: this is a *reductio ad absurdum*. Time forbids to say any more about the *B. coli commune*, and I am not here to discuss it.

I know of few organisms which are so indifferent with regard to the medium on or in which they are grown; aerobiosis or anaerobiosis, high or low temperatures, acid or alkaline reactions, light or darkness do not affect the *Bacteria coli* group to any marked degree. At the same time they are chemically extremely active organisms, and therefore their normal presence in the alimentary tract can hardly be of physiological indifference to us and animals. I incline to the belief that their influence in disease is secondary rather than primary, but I shall not discuss this point here.

Now, when we are dealing with organisms which are capable of growing and acting on dead as well as on living tissues, which are furthermore capable of great and varied chemical activity, and also resist external influences extremely well, and readily vary under such influences, it seems to me that an important point may be raised. If there be anything in adaptation, then I think the animal body must have adapted itself as much to the *Bacteria coli* group, as the latter, no doubt, has adapted itself to the animal body. The two organisms, viz. the *Bacterium coli* and the animal body must be well balanced; if the balance is disturbed, one of them must go down. Symbiosis, whether obligatory or facultative, is a problem which has hardly been touched upon as existing between man and low forms of germs. We know that plants make use of micro-organisms, and that vegetation is immensely assisted by nitrifying organisms. Under absolutely sterile conditions of growth a plant thrives badly. Experiments and observations are needed to show how animals would thrive on sterile food and in sterile surroundings. Pasteur, in 1885, expressed the opinion that they would do badly under such conditions. Nuttall and Thierfelder have shown that a guinea-pig brought aseptically into this world may be kept in good condition under sterile surroundings for 8 to 14 days, and from their experiments they argue that the presence of bacteria in the intestinal tract is not necessary to life. The obvious criticism is that a week or two for such experiments is too short a period, and that it would require observations carried on for months before it could be definitely stated whether or no bacteria are necessary not for life but for perfect development.

Fermi seems to incline towards a belief in a form of symbiosis existing between the *B. coli* group and the intestinal mucosa. There are observations which tend to show that lower forms of animal life do not grow or thrive well on sterile food. It seems possible from studying Neumeister's work on physiological chemistry, that some forms of bacteria—not necessarily the *B. coli commune*—are of use in assisting fermentative processes, and in aiding in the resorption and absorption of products of digestion, and it is certain that as putrefactive organisms they do good. Nor is it impossible that they are capable of splitting up certain toxic substances, thus rendering them harmless. The question of adaptation of the body to bacteria is well worthy of extended study; but while it is still a matter of speculation, it is safer to dismiss it with this brief allusion.

Taking a summary review of the points mentioned, we have seen that under ordinary conditions sound food often contains large quantities of bacteria, so that we habitually consume numberless micro-organisms. Further, the qualitative examination shows that we are habitually consuming such forms as the *B. coli commune* and *Proteus*. It is well that we should know the flora of apparently good food, and become familiarised with the idea, alarming to many, no doubt, that many articles of food daily consumed contain bacteria, some of which are described by bacteriologists as the typical organisms of the intestinal contents and of decomposing matter.

I do not wish to be misunderstood. I am not advocating the view that good food should be particularly rich in bacteria. All possible chance of direct fæcal, sewage, or other contamination should be, and must be, carefully avoided. On the other hand, we must not introduce a fictitious standard, and simply put on one side physiological facts and common-sense experience. Similarly we must pause before we give certain bacteria an absolutely specific significance which they possibly do not deserve.

The *B. coli commune* by itself does not prove sewage or fæcal pollution; it may and often does point to it, under certain conditions which Dr. Klein has recently defined, but it cannot unconditionally prove it. Again, its importance as the cause of enteritis must not be exaggerated. Thousands of *coli* bacilli are periodically taken in with the food, and they pass into an alimentary canal already full of these bacilli. This is a point worthy of consideration. True in an enteritis the *B. coli* may be found in pure culture in the dejecta, possessed of virulent properties when tested on the animal. This merely proves one of two things: if the *Bacterium coli* is the cause of the lesion then for some reason or another it must have been transformed from a harmless saprophyte into an irritant pathogenic organism; but it has not yet been shown that this organism is the cause of such a lesion, and therefore its abundant presence in such a lesion may be merely a concomitant phenomenon. The exact position of this extraordinary organism, or rather group of organisms, has not yet been exactly defined. Many observers may not agree with me; my own opinions are, however, based upon my personal acquaintance with the *Bacterium coli* and its varieties. It is of value in water or food examination, not because it is absolutely specific of bad or polluted food, but because it is easily recognised, and therefore its source can often

be traced. Food or water exposed to the danger of sewage or fæcal contamination, as for instance Thames water, containing a certain percentage of *B. coli commune*, cannot be said to be freed from all pollution. Further we cannot go.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE Head Masters' Conference at Rugby last week passed the following resolution unanimously:—"That the Conference deplores the time wasted in teaching boys the present system of weights and measures, and would welcome the introduction of a more rational system."

AMONG the French Universities which, in accordance with the new Act, will at the end of next year be permitted to dispose of the money accruing from students' fees, &c., the richest will be that of Lyons, which will thus have an annual income of over 5000*l*. According to the Paris correspondent of the *Chemist and Druggist*, schemes are already on foot for important educational extension in the capital of the centre. The Lyons Faculty of Medicine and Pharmacy, as well as the Faculty of Sciences, will probably be enlarged, and new laboratories built or the present ones extended. But the most important project is the construction of a Chemical Institute, in which will be reunited the various chemistry services of the two above-named faculties; and the already flourishing School of Commercial and Agricultural Chemistry will be also installed in this new building. The erection of this Institute will, it is hoped, be commenced next spring, and the cost is calculated at 60,000*l*., but the municipality will give the site, valued at 16,000*l*., and possibly other aid. The department has voted 2000*l*., and the State, it is hoped, will contribute over 25,000*l*. The head of the University states that, while laboratory research will not be neglected, the University will seek "to incorporate itself more and more with the industrial city" and "develop the technical instruction that may serve the commercial and manufacturing interests of a great city of half a million souls."

SCIENTIFIC SERIALS.

Wiedemann's Annalen der Physik und Chemie, No. 12.—Directed electric surface conductivity, E. Braun. Continuous transition of electric properties in the separating surface of solid and liquid bodies.—Conduction of electrified air. Magnetic currents. By the same author. Crystals have a different electric conductivity in different directions. This was proved by Wiedemann by dusting lycopodium powder on a cleavage surface and sending a spark from a wire into it. An elliptic area was cleared, with axes in a ratio varying from 1 : 2 to 1 : 3. The author obtained different surface conductivities with a steady current, through a layer of condensed moisture. The effect vanished when the thickness of the layer exceeded 50 $\mu\mu$. A steady transition from the polarisation properties of a solid to those of a fluid body may be traced in the surface layer.—Polarisation phenomena in vacuum tubes, by C. A. Mebius. When the current through a gas increases, the rate of fall of potential at the kathode increases more rapidly than at the anode. When secondary terminals are introduced, so as to give a transverse current, the rate of fall of potential at these decreases with an increase of the main current, when a current of a certain strength is sent through the secondary terminals.—On the transition of carbon from the non-conducting to the conducting condition, by G. Brion. The conductivity of carbon depends upon the highest temperature to which it is exposed, the time since elapsed, and the present temperature. It is acquired very rapidly at temperatures between 800° and 1000° C. The conductivity decreases rapidly during the first few hours after heating, and then more slowly.—On electro-capillary light, by O. Schott. On sending the sparks from an induction coil through a capillary tube 0·05 mm. in diameter containing air at ordinary pressure, an intense light is observed in the tube. The latter soon gets roughened and blown out into spherical bulbs. Wider tubes gave a less intense light, and are less altered. Electrodes of various metals may be used with the same effect. In the spectroscope, the light shows a continuous spectrum crossed by bright lines, and dark lines along the spectrum which shift their position at every discharge.—Glow-worm light, by H. Muraoka. Natural glow-worm light behaves like ordinary light. But when it is filtered through cardboard or through copper plates, it shows the properties of X-rays or Becquerel's fluorescence rays. The intensity of the action of the glow-worm rays is intensified by the presence of the cardboard near the sensitive plate. They may be reflected, and probably also refracted and polarised. The author operated with 300 glow-worms at Kyoto, Japan, during the month of June, when thousands of them swarm about the neighbourhood.—An attempt to demonstrate the existence of electrodynamic solar radiation, by J. Wilsing and J. Scheiner. Owing to the absorption of the longer waves by the atmosphere, and the consequent necessity for an instrument of extreme delicacy, the change of contact resistance between two metals was used as a test. But no positive results were obtained.

Bollettino della Società Sismologica Italiana, vol. ii., 1896, N. 4.—Recent observations and results on the form and mode of propagation of seismic waves, by Dr. A. Cancani.—The seismic data of Liguria, with reference to their frequency and periodicity, by Dr. E. Oddone.—On the after-shocks of the great Japanese earthquake of 1854, by Prof. F. Omori.—Notices of earthquakes occurring in Italy during the year 1896, by Prof. L. Palazzo. This catalogue, a continuation of that formerly compiled by Dr. M. Baratta for the Central Meteorological and Geodynamic Office at Rome, contains accounts of all the shocks recorded from January 1 to June 14. The more important are those of Polesina on March 8, near Florence on April 15, in Asia Minor on April 16, and several earthquakes of unknown and distant origin on March 4, April 10, and May 2, 3, and 5.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 10.—"On Prof. Hermann's Theory of the Capillary Electrometer." By George J. Burch, M.A.

In reply to the claim of Hermann (*Archiv für die Ges. Physiologie*, vol. lxiii. p. 440), that his theory of the capillary electrometer received confirmation from the author's experimental results, the author stated that his own theory was completed before he saw Hermann's paper, that it was based upon a totally different hypothesis, and that the identity of Hermann's equation with his own is due simply to the fact that both are the mathematical expression of a movement which is dead beat. Hermann, adopting Lippmann's polarisation theory, had assumed the simplest conceivable relation between the rate of polarisation and the acting P.D., namely, that they are proportional to one another. The author's starting point was the fundamental fact that in the capillary electrometer a mechanical effect is produced by an electrical cause. Writing Q for the quantity of electricity, C for the constant of capillarity, P for polarisation, and W for the work done, the symbolical expression of the problem is—

$$f(Q_t, C_t, P_t) = \phi(W_t).$$

Hermann has passed over C and omitted to take W into account, confining himself to the theoretical relation between Q_t and P_t. But the term polarisation includes two phenomena, viz.:—

(*a*) That condition of the interface between two conductors, of which one at least is an electrolyte, in which the molecules are under a stress not greater than they are capable of supporting without chemical change.

(*b*) A deposit upon the surface of a solid, or in the contiguous liquid, of the products of actual electrolysis.

If one of the conductors is a solid, the inevitable local differences of condition or of composition enable actual electrolysis to take place even with a P.D. smaller than that proper to the chemical change implied. But if both conductors are liquid and perfectly pure, the stress is so far equalised that no electrolysis is possible until the E.M.F. reaches a certain value, more sharply defined in proportion as the materials are pure. The author holds that with differences of potential which do not reach this limit, the electromotive force is transmuted, without electrolysis, into mechanical force, and manifests itself as kinetic energy, until by the motion of the meniscus it becomes transformed into potential energy. The locus of transformation from electrical to mechanical force must clearly be the two

interfaces mercury-acid and acid-mercury, and it is upon these that the stress acts. The resistance is distributed along the tube, and is partly electrical, but to a far larger extent mechanical. It does not seem reasonable, therefore, to assume that the sole cause of delay is the "polarisationsgeschwindigkeit" of the meniscus.

The author believes that in the case of an interface between two liquids, the rate of polarisation is to be measured in terms of the vibration period of a molecule, rather than in decimals of a second.

Actual electrolysis does not take place in a properly working electrometer, except with electromotive forces greater than ought to be employed.

According to the author, the capillary electrometer acts by transforming electrical into mechanical energy without any chemical interchange, this being possible because at the interface between two liquids which do not diffuse into each other the stress is so evenly distributed that no one molecule can be strained to a degree sufficient to detach any part of it until the stress is intense enough to break down all similar molecules simultaneously.

In order to investigate the motion of the meniscus under the action of a varying electromotive force, such as a pulsating or alternating current, Hermann puts his equation into the form

$$\frac{dp}{dt} + rp - re f(t) = 0,$$

which is identical with the author's formula for the estimation of the E.M.F., viz.—

$$N + k\Delta r = \frac{1}{0{\cdot}0133} \times f(t) \text{ volt},$$

i.e.

$$\left\{\begin{array}{c}\text{The sub-}\\\text{normal}\\\text{to the curve}\end{array}\right\} + \left\{\begin{array}{c}\text{A constant}\\\text{multiple of the}\\\text{distance from}\\\text{the zero line}\end{array}\right\} = \left\{\begin{array}{c}\text{A constant}\\\text{multiple of}\end{array}\right\} \left\{\begin{array}{c}\text{The}\\\text{E.M.F.}\\\text{at time } t\\\text{in volts.}\end{array}\right\}$$

From this formula it is evident at once that the E.M.F. is zero whenever $N = -k\Delta r$, and that the crossing of the zero line by the mensicus must always lag behind the change of sign of the E.M.F. Hence the curve can never come back to the zero line under the action of a current which pulsates but does not alternate. When N, *i.e.* $\frac{dp}{dt}$ vanishes, as it does at the apex of a spike or the bottom of a notch, the instantaneous value of the impressed E.M.F. is directly proportional to the distance of the meniscus from zero. The author has proposed that this method should be used to determine the characteristic current curves of dynamos.[1]

Royal Meteorological Society, December 16.—Mr. E. Mawley, President, in the chair.—An interesting paper, by Dr. Leigh Canney, on the winter climate of Egypt, was read by the Secretary. The climate of Egypt during the winter is influenced by the Libyan desert, by the Mediterranean Sea, and by the extent of cultivated land. The author gave the results of a series of observations which he had carried on during the past three winters. The observations were started with the object of arriving at a comparative knowledge respecting the climates of the various stations now considered as health resorts in Egypt, and by a strictly comparable method to arrive at the precise differences between the climates of Upper and Lower Egypt, all previous observations having failed in this respect. The stations at which observations were made were Cairo, Helouan, Mena House Hotel, Luxor, Assouan, Valley of the Tombs of the Kings, and the crest of the Libyan Hills. As self-recording thermometers and hair hygrometers were used at each station, valuable data have been obtained on the diurnal variation of temperature and humidity.—Mr. R. H. Curtis also read a paper on an attempt to determine the velocity equivalents of wind forces estimated by Beaufort's scale. The author has compared the anemometric records at Scilly, Fleetwood, Yarmouth, and Holyhead, with the wind forces as estimated by the observers at the same or adjoining stations, and has by this method obtained a satisfactory table of velocity equivalents in miles per hour for the estimated forces by Beaufort's scale.

[1] "The Capillary Electrometer in Theory and Practice." (Reprinted from the *Electrician* of July 17 *et seq.*, 1896.)

Geological Society, December 16.—Dr. Henry Hicks, F.R.S., President, in the chair.—On the subdivisions of the carboniferous series in Great Britain, and the true position of the beds mapped as the Yoredale series, by Dr. Wheelton Hind. In this paper the author gave a summary of the knowledge of the local division of the Carboniferous system, and criticised the present classifications in vogue, laying special stress upon the local variations in the lithological characters of the rocks, and summing up to a large extent the fossil evidence which is available. He maintained that the Yoredale beds were largely the equivalents of the beds which had elsewhere been referred to the Mountain Limestone series, though some local beds which had been included in the Yoredale series might rather be the equivalents of the millstone grit. He would divide the rocks of the Carboniferous system into an Upper Carboniferous or Anthraciferous series, and a Lower Carboniferous or Calcareous series; and indicated the occurrence of three very different faunas in the Carboniferous rocks, viz.: (1) a Coal-Measure fauna rich in fish remains; (2) the Lower Coal-Measure and Grit fauna, largely marine but littoral; and (3) a Limestone fauna, essentially marine, very rich in brachiopods.—Note on volcanic bombs in the Schalsteins of Nassau, by Prof. E. Kayser. The bombs forming the subject of this communication occurred in two localities in the neighbourhood of Oberscheld near Dillenburg. They were generally rounded, though sometimes angular, and varied in size from that of a nut to that of a man's head. Each consisted of a kernel of coarse-grained rock representing a fragment of limestone altered by metamorphism, surrounded by a rind of amygdaloidal rock due to the inclusion of the fragment in molten lava. They demonstrated the pyroclastic origin of the Schalsteins, and also proved the similarity between the old Devonian volcanoes and those which were now active.

MANCHESTER.

Literary and Philosophical Society, December 15.—Prof. H. B. Dixon, F.R.S., in the chair.—Mr. J. C. Melvill read a paper on a collection of marine mollusca, mostly dredged by Mr. F. W. Townsend, who is officially connected with the Indian Oceanic Telegraph Company, whose cable extends from Kurachi to Bushire in the Persian Gulf. Mr. Townsend has made good use of the exceptional facilities he possesses for thus dredging the marine fauna, some forms being obtained attached to the cable itself, and some dredged in shallow, others in deep, water. The collections are of first-rate importance to the malacologist, the more so as this part of the North Indian Ocean has been curiously neglected in the past; the results have not yet been fully examined, but no less than thirty-two forms were described and differentiated as new to science. Of these the principal belonged to the genera *Nassa*, *Sistrum*, *Terebra* (one extraordinary form), *Mitra* (also very unusual in appearance), *Turritella*, *Coralliophila*, many *Trochi*, *Dentalium*, and, amongst Pelecypoda, *Yoldia* (a particularly interesting tropical form of an Arctic genus), *Pectunculus*, *Tellina*, *Donax*, *Chione*, and others.—On the ampullæ on specimens of *Millepora* in the Manchester Museum, by Prof. S. J. Hickson, F.R.S. The author stated that he had discovered ampullæ on several specimens in the museum. At least one of these belongs to the West Indian species *M. alcicornis*, and the observation suggests that all species of *Millepora* at some time produce medusæ similar to those of the Pacific Ocean species *M. murrayi*.

PARIS.

Academy of Sciences, December 21.—Annual Meeting.—M. A. Cornu in the chair.—The President's address was chiefly occupied with an historical retrospect of the X-rays. The losses by death during the year include the names of Fizeau, Tisserand, Reiset, Sappey, Daubrée, Resal, and Trécul.—The Arago medal has been awarded twice during the year, to M. A. Abbadie and to Lord Kelvin. The prizes offered for the present year have been awarded as follows:—In the section of Mathematics, the grand prize to M. E. Maillet for his work on the theory of substitutions, the Bordin prize to M. Jacques Hadamard for his memoir on the theory of geodesic lines, the Francœur prize to M. A. Valson, and the Poncelet prize to M. Painlevé for general contributions to mathematics. In the section of Mechanics, the extraordinary prize of 6000 fr. is divided between MM. Darrieus (for a work on the improvement of the naval forces),

Baule (for the application of the gyroscope to the determination of the altitudes of stars at sea), Schwerer, Blot, Monaque, Morache, Paqué, Terrier, and de Vanssay (for their magnetic observations). M. Henry Parenty receives a Montyon prize for his experimental researches on the theory of fluids, and M. Marbec the Plumey prize for his memoir on some applications of graphical mechanics. In Astronomy, the Lalande prize is given to M. P. Puiseux (for his selenographical work), the Valz prize to M. Bossert (for his reduction of older observations previously inaccessible), and the Janssen prize to M. Deslandres (for his studies in spectroscopy). No memoirs were received for the Damoiseau prize. In Statistics, a Montyon prize is taken by M. Huguet (for his study of the statistics of voluntary mutilation and assumed diseases in the army), and another by the *Comité des Compagnies d'Assurances a prime fixes sur la vie* (for a report on the tables of mortality used by them). In Chemistry, the Jecker prize is divided between MM. Matignon (for his thermochemical studies), V. Auger (for his researches on the chlorides of dibasic acids), M. Bouveault (for researches on the nitriles), and M. Genvresse (for work in organic chemistry). In the section of Mineralogy and Geology a Vaillant prize, which was offered for an experimental study of the physical and chemical causes which determine the existence of rotatory power in transparent substances, is awarded to M. Ph. A. Guye, and another, for which the subject of the theoretical and practical improvement in the methods of geodesy or topography was suggested, to M. C. Lallemand, for his contributions to the methods of levelling; whilst the Fontannes prize is given to M. Douvillé for his stratigraphical and palæontological researches. In the Botanical section M. E. Bescherelle receives the Desmazières prize, and M. Flagey a Montagne prize. In the section of Anatomy and Zoology, the Thore prize is taken by M. C. Janet, the Savigny prize not being awarded. In Medicine and Surgery, Montyon prizes are taken by M. Laskowski, for an anatomical atlas, by M. Legrain, for his studies on alcoholism, by MM. Imbert and Bertin-Sans, and MM. Oudin and Barthélemy, for their applications of the Röntgen rays in surgery and medicine. Honourable mentions are accorded to MM. Comby, Brocq and Jacquet, Broca and Maubrac. The Barbier prize is divided between MM. Bertrand and Fontan, and M. Raynaud; the Breant prize between M. Rénon and MM. Netter and Thoinot. The Godard prize is awarded to M. Max Melchior for his contribution on urinary infection, M. P. Delbet receiving an honourable mention. The Serres prize is divided equally between MM. Mathias Duval and Alfred Giard for their embryological studies, whilst M. Brun receives the Bellion prize, an honourable mention being accorded to M. Bodin. The Mège prize is awarded to M. Mauclaire, the Lallemand prize to M. R. Dubois, and the Baron Larrey prize to M. Edm. Delorme. In Physiology, M. Contejean receives a Montyon prize for his work on gastric digestion, Dr. Joachimsthal the Pourat prize for his experimental work on the locomotive apparatus, and M. Tissot, the Philipeaux prize for his study of the gaseous exchanges in isolated muscle. In the section of Geographical Physics, M. André Delebecque receives the Gay prize for his study of the French lakes. Of the general prizes, a Montyon prize is awarded to M. E. Cacheux for his construction of healthy workmen's dwellings, and other labours in connection with the improvements in the health and conditions of life of the working classes; the Trémont prize to M. Charles Frémont for his experiments on the effects of punching on metals; the Gegner prize to M. Paul Serret; the Delalande-Guérineau prize to M. Toutée for the scientific results of his expedition on the Niger; the Jean Reynaud prize to M. Henri Poincaré; the Jérome Ponti prize to MM. Benoit, Chapuis, and Guillaume, for the metrological work done in the International Metric Bureau at Breteuil; the Leconte prize (arrears) to M. Roussel, for his geological work in the Pyrenees, and to M. Henneguy for his researches on the development of the bony fishes; the Tchihatchef prize to Prince Henri d'Orleans, for his geographical work in Central Asia; the Houllevigue prize to M. Joannis, for his chemical researches; the Cahours prize to MM. Freundler, Lebeau, Hébert, and Varet; the Saintour prize to M. Renault, for his memoirs on vegetable palæontology and fossil bacteria, and to M. Guntz for his researches on fluorides, the alkali metals, and absorption of hydrogen and nitrogen by lithium; the prize founded by Mme. la Marquise de Laplace, to M. de Nanteuil de la Morville; and the prize founded by M. Félix Rivot, to MM. de Nanteuil de la Morville, Dutilleul, Balling, and Leroux.

DIARY OF SOCIETIES.

PHYSICAL SCIENCE A HUNDRED YEARS AGO.

Humphry Davy, Poet and Philosopher. By T. E. Thorpe, LL.D., F.R.S. (Century Science Series) Pp. 240. (London: Cassell and Co., Ltd., 1896.)

THE time is now fast approaching when people will be reckoning up the achievements of the closing century. Undoubtedly the great characteristic of the times in which we and our fathers and grandfathers have lived is the enormously rapid advance which has been made in our knowledge of the earth itself and of the forces of nature. Middle-aged people can remember the time when trains were much less frequent and rapid, the telegraph a rather expensive luxury, and when telephones were not. If they happen to have crossed the ocean in a modern "liner," or have heard of what can be done with modern explosives, or chance to have fallen into the hands of the modern surgeon or physician armed with anæsthetics, antiseptics and hypnotics fresh from the laboratory of the synthetical chemist, they are ready to acknowledge that things are greatly changed since their young days. But it is only after the perusal of such a book as this, that the ordinary reader comes to realise that all these things are not belated inventions which ought to have been given to us sooner, but that the very foundations of all physical science were hardly laid a hundred years ago. If we try to sum up the position in 1796, we find that though some advance had been made in theoretical mechanics and dynamics, there was very little knowledge about heat, light, electricity, or chemistry. It was known, for example, that if sulphur, glass, or sealing-wax was rubbed, or bits of zinc and copper immersed in salt and water, sparks and shocks could be got out of the arrangement, but up to 1800 the phenomena of electrolysis were wholly unknown, and not till even later were the magnetic properties of the current discovered The "corpuscular" theory of light held its own till the early days of the nineteenth century, and "caloric" was still regarded as a sort of matter which could enter into chemical combinations, and could be squeezed out of bodies like water from a sponge. Chemistry at the same time was only just emerging from the disorder attending the dying struggles of the phlogistic doctrine, and even the Lavoisierian system, which had taken its place, was disfigured by many errors which could only be rectified by a long series of experiment more exact than anything which had ever before been possible.
